# Smith's Textbook of Endourology

# Smith's Textbook of Endourology

## Fourth Edition

## VOLUME 1

**Edited by**

*Arthur D. Smith, MD*
*Professor of Urology*
*The Arthur Smith Institute for Urology*
*Zucker School of Medicine at Hofstra/Northwell*
*Lake Success, NY, USA*

*Glenn M. Preminger, MD*
*James F. Glenn Professor of Urology and Chief*
*Division of Urology, Department of Surgery*
*Duke University Medical Center*
*Durham, NC, USA*

*Louis R. Kavoussi, MD*
*Waldbaum Gardner Professor and Chairman*
*The Arthur Smith Institute for Urology*
*Zucker School of Medicine at Hofstra/Northwell*
*Lake Success, NY, USA*

*Gopal H. Badlani, MD, FACS, FRCS (Hon)*
*Vice Chair Urology*
*Professor of Urology and Gynecology*
*Wake Forest University*
*Winston-Salem, NC, USA*

**Assistant Editor**

*Ardeshir R. Rastinehad, DO, FACOS*
*Associate Professor of Urology and Radiology*
*Director of Focal Therapy and Interventional Urologic Oncology*
*Department of Radiology and Urology*
*Icahn School of Medicine at Mount Sinai*
*New York, NY, USA*

**List of Contributors** *xvi*
**Foreword** *xl*
**Preface** *xli*
**About the Companion Website** *xliii*

## VOLUME 1

### SECTION 1 BASIC PRINCIPLES

1 **Care and Sterilization of Instruments** *3*
*Carol Olsen*

2 **Radiation Safety During Diagnosis and Treatment** *14*
*Yasser A. Noureldin & Sero Andonian*

3 **Enhanced Endoscopic Imaging** *38*
*Ghalib A. Jibara & Michael E. Lipkin*

4 **Preoperative Antibiotics and Prevention of Sepsis in Urologic Endoscopic Surgery** *57*
*Manish N. Patel & Jorge Gutierrez-Aceves*

5 **Management of the Anticoagulated Patient** *73*
*Zeph Okeke*

### SECTION 2 PERCUTANEOUS RENAL SURGERY
### Part 1 Perioperative Considerations

6 **Surgical Anatomy of the Kidney for Endourological Procedures** *87*
*Francisco J.B. Sampaio*

7 **Nephrolithometric Scoring Systems for Percutaneous Nephrolithotomy** *108*
*Roshan Patel, Daniel J. Lama, & Zhamshid Okhunov*

8 **Pathophysiology of Urinary Tract Obstruction** *124*
*Frederick A. Gulmi & Diane Felsen*

9 **Organizing the Endourological Operating Room** *143*
*Ravindra B. Sabnis, Abhishek Singh, & Shashikant Mishra*

10 **Endoscopic Training/Simulation** *159*
*Zichen Zhao & Robert M. Sweet*

## Part 2 Patient Positioning for Percutaneous Access

11 **Patient Positioning, the Supine Position, and the Rationale of ECIRS** *173*
*Cesare M. Scoffone & Cecilia M. Cracco*

12 **Prone, Lateral, and Flexed: Patient Positioning for Percutaneous Nephrolithotomy** *185*
*Robert J. Sowerby, A. Andrew Ray, & R. John D'A. Honey*

## Part 3 Imaging for Access

13 **Percutaneous Nephrolithotomy Access Under Fluoroscopic Control** *210*
*Norberto O. Bernardo & Maximiliano Lopez Silva*

14 **Dyna-CT-Guided versus Standard CT-Guided Renal Access** *221*
*Manuel Ritter & Maurice-Stephan Michel*

15 **Endoscopically Guided Percutaneous Renal Access** *229*
*Zhamshid Okhunov, Kamaljot S. Kaler, Simone Vernez, Rahul Dutta, Jaime Landman, & Ralph V. Clayman*

16 **Percutaneous Nephrolithotomy Access Under Ultrasound** *237*
*Mahesh R. Desai & Arvind P. Ganpule*

17 **New Concepts of Renal Access: iPad, GPS, and Others** *244*
*Estevao Lima, Pedro L. Rodrigues, Marie-Claire Rassweiler-Seyfried, & João L. Vilaça*

## Part 4 Selection of Access and Dilation

18 **Percutaneous Nephrolithotomy: Upper Pole Access** *255*
*Davis P. Viprakasit & Nicole L. Miller*

19 **Percutaneous Nephrolithotomy Access Without Image Guidance** *264*
*Arthur D. Smith*

20 **Percutaneous Nephrolithotomy Access: Robotic** *269*
*Michelle Jo Semins, Dan Stoianovici, & Brian R. Matlaga*

21 **Dilation of the Nephrostomy Tract** *275*
*Peter Alken*

## Part 5 Stone Removal

22 **Rigid and Flexible Nephroscopy** *285*
*Timothy Y. Tran & Mantu Gupta*

23 **Percutaneous Antegrade Ureteroscopy** *294*
*Burak Turna, Umit Eskidemir, & Oktay Nazli*

24 **Small-caliber Percutaneous Nephrolithotomy: Mini, UMP, and Micro-Perc** *301*
*Janak D. Desai & Arkadiusz Miernik*

25 **Percutaneous Nephrolithotomy: Special Problems with Staghorns** *310*
*Monica A. Farcas & Kenneth T. Pace*

26 **Percutaneous Nephrolithotomy: Stone Extraction and Lithotripsy** *322*
*Samir Derisavifard & Arthur D. Smith*

27 **Percutaneous Nephrolithotomy in Children** *332*
*Adam S. Howe, Jordan S. Gitlin, & R. John D'A. Honey*

**Part 6 Other Uses of Nephrostomy Access**

28 **Percutaneous Nephrolithotomy of Calyceal Diverticula, Infundibular Stenosis, and Simple Cysts** *341*
*Nadya E. York & James E. Lingeman*

29 **Percutaneous Instillation of Chemolytic, Chemotherapeutic, and Antifungal Agents** *353*
*Mohamed A. Elkoushy, Philippe D. Violette, & Sero Andonian*

30 **Percutaneous Treatment of Ureteropelvic Junction Obstruction** *377*
*Michael W. Sourial, Bodo E. Knudsen, & Paul J. Van Cangh*

31 **Percutaneous Management of Upper Tract Urothelial Carcinoma** *384*
*Shu Pan & Piruz Motamedinia*

**Part 7 Exit Strategy and Complications**

32 **The Access-related Complications of Percutaneous Nephrolithotomy** *390*
*Vinaya Vasudevan, Zeph Okeke, & Arthur D. Smith*

33 **Hemorrhagic Complications Associated with Percutaneous Nephrolithotomy** *397*
*Sriram V. Eleswarapu & David A. Leavitt*

34 **Diagnosis and Management of Thoracic Complications of Percutaneous Renal Surgery** *409*
*John R. Bell & Stephen Y. Nakada*

35 **Bowel and Other Organ Injuries with Percutaneous Nephrolithotomy** *422*
*John J. Knoedler, Matthew T. Gettman, & Chad J. Fleming*

36 **Exit Strategies After Percutaneous Nephrolithotomy** *427*
*Damien M. Bolton & Derek B. Hennessey*

37 **Problems with Residual Stones** *441*
*Noah E. Canvasser & Margaret S. Pearle*

**SECTION 3 URETEROSCOPY**
**Part 1 General Principles**

38 **Ureteral Anatomy** *455*
*Gary Faerber, Amir H. Lebastchi, & Rita P. Jen*

39 **Rigid Ureteroscopes** *465*
*Omar M. Aboumarzouk & Francis X. Keeley, Jr.*

40 **Flexible Ureteroscopes** *475*
*Vincent G. Bird & John M. Shields*

41 **Rigid Ureteroscope with Flexible Tip and Special Instrumentation** *486*
*Yinghao Sun & Xiaofeng Gao*

42 **Digital Ureteroscopes** *497*
*Murat Binbay & Burak Ucpinar*

43 **Ureteroscopy Working Instruments** *506*
*Renato N. Pedro & Manoj Monga*

44 **Access to the Ureter: Rigid Ureteroscopy** *514*
*Jose De La Cerda, III & Timothy Y. Tseng*

45 **Access to the Ureter: Flexible Ureteroscopy** *521*
*Ojas Shah & Mark V. Silva*

46 **Ureteroscopy Energy Sources** *532*
*Daniel A. Wollin & Glenn M. Preminger*

47 **Ureteroscopic Management of Ureteral Calculi** *542*
*Charles U. Nottingham, Melanie A. Adamsky,*
*Richard J. Fantus, & Glenn S. Gerber*

48 **Ureteroscopic Management of Renal Calculi** *549*
*Steeve Doizi & Olivier Traxer*

49 **Diagnostic Ureteroscopy** *562*
*Hendrik Heers & Benjamin W. Turney*

50 **Ureteroscopic Diagnosis and Treatment of Upper Urinary Tract Neoplasms** *568*
*Scott G. Hubosky & Demetrius H. Bagley*

**Part 2 Ureteroscopic Management of Ureteral Obstruction**

51 **Retrograde Endopyelotomy** *584*
*Weil R. Lai & Raju Thomas*

52 **Endoscopic Management of Mid-ureteral Obstruction** *592*
*Samuel Abourbih & D. Duane Baldwin*

53 **Endoscopic Management of Distal Ureteral Strictures** *604*
*Michael Zhang, Ali Fathollahi, Joel Hillesohn, & Majid Eshghi*

54 **Endoscopic Management of Ureteroenteric Strictures** *629*
*Thomas Masterson & Robert Marcovich*

55 **Ureterorenoscopy: Ureteral Stents and Postoperative Care** *642*
*Ben H. Chew, Anthony Emmott, Dirk Lange, & Ryan F. Paterson*

56 **Ureteroscopy Complications** *653*
*Joel E. Abbott & Roger L. Sur*

57 **Retrograde Intrarenal Surgery in the Future: Robotics** *668*
*Anup Patel*

## SECTION 4 SHOCK-WAVE LITHOTRIPSY

**58** **Physics of Shock-wave Lithotripsy** *691*
*Andreas Neisius & Pei Zhong*

**59** **Lithotripsy Systems** *713*
*Geert G. Tailly*

**60** **Shock-wave Lithotripsy of Renal Calculi** *731*
*Brian H. Eisner & Naren Nimmagadda*

**61** **Shock-wave Lithotripsy of Ureteral Calculi** *745*
*Thomas Tailly & Hassan Razvi*

**62** **Complications of Shock-wave Lithotripsy** *756*
*Christian Türk & Aleš Petřík*

## SECTION 5 STONE MANAGEMENT IN UROLOGY
### Part 1 General Principles

**63** **Natural History of Stones** *765*
*Johann P. Ingimarsson & Amy E. Krambeck*

**64** **Initial Choice of Therapy in the Stone Patient** *777*
*Peter L. Steinberg & David M. Hoenig*

**65** **Management of Urolithiasis in Pregnancy** *786*
*Husain Alenezi & John D. Denstedt*

**66** **Management of Renal Colic and Triage in the Emergency Department** *798*
*Marius C. Conradie*

### Part 2 Management of Stones in Abnormal Situations

**67** **Management of Stones in Horseshoe Kidneys** *811*
*Chandra Shekhar Biyani & Adrian D. Joyce*

**68** **Pelvic Kidneys** *818*
*Win Shun Lai, Vidhush K. Yarlagadda, & Dean G. Assimos*

**69** **Management of Stone Disease in Renal Transplant Kidneys** *827*
*Brian Duty & Michael Lam*

**70** **Stones in Urinary Diversions** *836*
*Bodo E. Knudsen & Michael W. Sourial*

**71** **Management of Stones in Obesity** *843*
*Omer L. Tuncay & Cenk Acar*

### Part 3 Cost-effectiveness and Long-term Stenting

**72** **Cost-effective Strategies for Stone Management** *853*
*Justin I. Friedlander & Eric M. Ghiraldi*

73 **Long-term Stenting of the Ureter** *864*
*Panagiotis Kallidonis, Wissam Kamal, Dimitrios Kotsiris, Dimitrios Karnabatidis, & Evangelos Liatsikos*

**Index** *i1*

## VOLUME 2

### SECTION 6 LAPAROSCOPY AND ROBOTIC SURGERY

### Part 1 General Principles

74 **New Surgical Robotics** *881*
*Alabdulaali Ibrahim & Koon Ho Rha*

75 **Training and Credentialing Laparoscopic and Robotic Surgery** *887*
*Domenico Veneziano & David M. Hananel*

76 **Patient Preparation and Operating Room Setup for Laparoscopic and Robotic Surgery** *901*
*Weil R. Lai & Benjamin R. Lee*

77 **Patient Preparation and Operating Room Setup for Robotic Surgery** *909*
*Dima Raskolnikov, Mahir Maruf, & Arvin K. George*

78 **Physiologic Considerations in Laparoscopic and Robotic Surgery** *917*
*Adam G. Kaplan & Michael N. Ferrandino*

79 **Anesthetic Management During Laparoscopic/Robotic Surgery** *928*
*Judith Aronsohn, Oonagh Dowling, & Greg Palleschi*

### Part 2 Instrumentation, Access, and Exit

80 **Laparoscopic Surgery: Basic Instrumentation** *944*
*Ornob Roy*

81 **Robotic Surgery: Basic Instrumentation and Troubleshooting** *954*
*Wooju Jeong, Mouafak Tourojman, & Craig G. Rogers*

82 **Minimally Invasive Reconstructive Techniques: Suture, Staple, and Clip Technology** *960*
*Ali Abdel Raheem & Koon Ho Rha*

83 **Transperitoneal Access and Trocar Placement** *973*
*Angelo Territo & Alberto Breda*

84 **Retroperitoneal Access and Trocar Placement** *987*
*Lambros Stamatakis & Soroush Rais-Bahrami*

85 **Basic Hand-assisted Laparoscopic Techniques** *994*
*Sapan N. Ambani & J. Stuart Wolf, Jr.*

86 **Laparoscopic Exit: Specimen Removal, Closure, and Drainage** *1010*
*Fernando J. Kim, Riccardo Autorino, & Rodrigo Donalisio da Silva*

### Part 3 Complications

87 **Complications in Urologic Laparoscopy** *1021*
*David Canes, Camilo Giedelman, & Rene J. Sotelo*

88 **Complications of Laparoscopy Including Robotics** *1032*
*Friedrich-Carl von Rundstedt, Marcelo Chen, & Richard E. Link*

## Part 4 Laparoscopy/Robotics for Malignant Disease

89 **Pelvic Lymphadenectomy** *1048*
*Marc D. Manganiello & Andrew A. Wagner*

90 **Endoscopic Subcutaneous Modified Inguinal Lymph Node Dissection for Squamous Cell Carcinoma of the Penis** *1060*
*Jay T. Bishoff & Kefu Du*

91 **Laparoscopic and Robotic Retroperitoneal Lymph Node Dissection** *1066*
*James R. Porter*

92 **Laparoscopic Radical Nephrectomy** *1077*
*Simpa S. Salami*

93 **Robotic Partial Nephrectomy: Advancements and Innovations** *1088*
*Sameer Chopra, Mehar Bains, & Inderbir S. Gill*

94 **Intraoperative Assessment of Tumor Resection Margins** *1097*
*Ilan Z. Kafka & Timothy D. Averch*

95 **Laparoscopic Radical Nephroureterectomy** *1101*
*Wayland J. Wu & Jessica E. Kreshover*

96 **Laparoscopic and Robotic Radical Cystectomy in Males and Females** *1107*
*Douglas S. Scherr, David M. Golombos, & Abimbola Ayangbesan*

97 **Robot-assisted Laparoscopic Partial Cystectomy** *1115*
*Manish A. Vira & Paras H. Shah*

98 **Laparoscopic Cystoprostatectomy with Intracorporeal Ileal Conduit** *1125*
*Alvin C. Goh, Brian J. Miles, & Arun Rai*

99 **Laparoscopic/Robotic Continent Diversion** *1128*
*Christopher R. Reynolds & Ashok K. Hemal*

100 **Laparoscopic Radical Prostatectomy** *1140*
*Jens Rassweiler, Giovannalberto Pini, Marcel Fiedler, Ali Serdar Goezen, & Dogu Teber*

101 **Robot-assisted Laparoscopic Radical Prostatectomy** *1169*
*Zeyad Schwen & Misop Han*

102 **Optimizing Outcomes During Laparoscopic and Robot-assisted Radical Prostatectomy** *1179*
*Matthew Goland-Van Ryn, Daniel Rosen, Thomas Bessede, & Ashutosh Tewari*

## Part 5 Laparoscopy/Robotics for Benign Disease

103 **Laparoscopic and Robotic Reconstructive Ureteral Surgery: Basic Principles** *1194*
*Aaron C. Weinberg, Yuka Yamaguchi, Lee C. Zhao, & Michael D. Stifelman*

104 **Laparoscopic Applications to Renal Calculus Disease** *1208*
*Christopher S. Han & Sammy E. Elsamra*

105 **Laparoscopic Treatment of Renal Cysts and Diverticula** *1221*
*Salvatore Micali, Eugenio Martorana, Giacomo Maria Pirola, & Giampaolo Bianchi*

106 **Laparoscopic and Robotic Techniques for Management of Pelvic Organ Prolapse** *1234*
*Sandeep Gurram & Farzeen Firoozi*

107 **Laparoscopic and Robotic Techniques for Repair of Female Genitourinary Fistulas** *1242*
*Chad Baxter & Vishnukamal Golla*

108 **Laparoscopic, Laparoendoscopic Single-site, and Robot-assisted Living Donor Nephrectomy** *1250*
*Ganesh Sivarajan & Ravi Munver*

109 **Robotic Kidney Transplantation** *1259*
*Rajesh Ahlawat, Sohrab Arora, & Mani Menon*

110 **Minimally Invasive Surgery for Benign Prostate Disease: Laparoscopic and Robotic Techniques** *1269*
*Mark Ferretti, Amul Bhalodi, & John Phillips*

111 **Laparoscopic Adrenalectomy** *1278*
*Tadashi Matsuda, Hidefumi Kinoshita, Yoshihide Kawasaki, & Akira Miyajima*

112 **Laparoscopic and Robotic Surgery of the Seminal Vesicles** *1292*
*Eric H. Kim, R. Sherburne Figenshau, & Gerald L. Andriole*

113 **Modern Techniques in Abdominal Wall Hernia Repair: a Guide for the Practicing Endourologist** *1299*
*Douglas K. Held*

114 **Robot-assisted Vasectomy Reversal** *1313*
*Parviz K. Kavoussi*

**Part 6 Laparoscopy/Robotics in Children**

115 **Laparoscopic Considerations in Children** *1323*
*Rajeev Chaudhry, Michelle Yu, & Michael C. Ost*

116 **Laparoscopic and Robotic Pyeloplasty in Children** *1328*
*Kai-wen Chuang*

117 **Lower Ureteral Reconstruction: Robotic Surgery** *1335*
*S. Duke Herrell*

118 **Laparoscopic Management of the Undescended Testicle** *1344*
*Brian A. VanderBrink*

119 **Laparoscopic Varicocelectomy** *1353*
*Bradley A. Morganstern & Lane S. Palmer*

**Part 7 Laparoscopy and Robotics: LESS and NOTES**

120 **Laparoendoscopic Single-site Surgery: Ports, Access, and Instrumentation** *1361*
*Noah E. Canvasser & Jeffrey A. Cadeddu*

121 **Laparoendoscopic Single-site Upper Tract Surgery** *1373*
*Christian Tabib, Geoffrey Gaunay, & Lee Richstone*

122 **Robotic Laparoendoscopic Single-site Lower Tract Surgery** *1385*
*Daniel Ramirez, Matthew J. Maurice, & Jihad H. Kaouk*

## SECTION 7 IMAGE-GUIDED DIAGNOSTICS AND THERAPEUTICS

### Part 1 Upper Tract

123 **Diagnosis of Renal Masses: Radiological** *1393*
*Gail S. Smith, Carolyn K. Donaldson, & Richard M. Gore*

124 **Renal Mass Biopsy** *1425*
*M. Pilar Laguna & Jean de la Rosette*

125 **Radiofrequency Ablation of Renal Tumors** *1442*
*Ryan L. Steinberg & Chad R. Tracy*

126 **Percutaneous Cryoablation of Renal Masses** *1454*
*David N. Siegel & Alok A. Anand*

### Part 2 Angio-embolization in Urology

127 **Gonadal Vein Embolization** *1464*
*Pratik A. Shukla, Gajan Sivananthan, & Ardeshir R. Rastinehad*

128 **Renal Angiography and Embolization** *1479*
*Igor Lobko & Anthony D. Mohabir*

129 **Selective Arterial Prostate Embolization** *1488*
*Robert C. Blue, Aaron M. Fischman, & Ardeshir R. Rastinehad*

### Part 3 Focal Therapy Lower Tract

130 **The Role and Methodology of Multiparametric MRI and Fusion-guided Biopsy in the Management of Prostate Cancer Patients** *1495*
*Raju R. Chelluri, Arvin K. George, Joseph A. Baiocco, Baris Turkbey, & Peter A. Pinto*

131 **Focal Therapy of Prostate Cancer** *1509*
*Kae Jack Tay & Thomas J. Polascik*

132 **Focal Laser Ablation for Carcinoma of Prostate** *1523*
*Tonye A. Jones, Shyam Natarajan, & Leonard S. Marks*

133 **Image-guided Prostate Brachytherapy** *1534*
*Michael R. Folkert, Neil B. Desai, & Yoshiya Yamada*

134 **Image-guided External Beam Radiotherapy** *1550*
*Brett Cox, Lucille Lee, & Louis Potters*

135 **High-intensity Focused Ultrasound of the Prostate** *1567*
*Edward J. Bass, Mark Emberton, & Hashim U. Ahmed*

**136** **Cryotherapy of the Prostate** *1580*
*Daniel B. Rukstalis*

**137** **Cryosurgical Ablation of the Prostate** *1589*
*Rajan Ramanathan, Yaw A. Nyame, & J. Stephen Jones*

**138** **Contrast-enhanced Ultrasound in Urology** *1605*
*Rogier R. Wildeboer, Jean de la Rosette, Massimo Mischi, & Hessel Wijkstra*

**139** **Principles of Prostate Magnetic Resonance Imaging** *1616*
*Sonia Gaur, Baris Turkbey, & Peter L. Choyke*

**140** **Male Lower Urinary Tract Symptoms and Assessment** *1627*
*Henry Tran, Matthew P. Rutman, Doreen E. Chung, & Jerry G. Blaivas*

**141** **Office-based Cystoscopy: Continued Advances** *1643*
*Judson D. Davies & Sam S. Chang*

**142** **Equipment Setup and Patient Handouts** *1649*
*John R. Schwabe, Amanda P. Hughes, Crystal R. Combs, & Gopal H. Badlani*

**143** **Local Anesthesia for Minimally Invasive Treatment of the Prostate in the Office Setting** *1661*
*Arun Rai & Ricardo R. Gonzalez*

**144** **Laser in Benign Prostatic Hyperplasia Treatment: Basic Principles** *1672*
*Christopher Netsch, Bilal Chughtai, Alexis E. Te, Ahmed M. Elshal, Mostafa M. Elhilali, & Andreas J. Gross*

**145** **Holmium Laser Therapy of the Prostate** *1681*
*Ahmed M. Elshal & Mostafa M. Elhilali*

**146** **532 nm High-power Transurethral Laser Prostatectomy** *1693*
*Bilal Chughtai, Dominique Thomas, & Alexis E. Te*

**147** **Thulium Lasers** *1707*
*Andreas J. Gross & Christopher Netsch*

**148** **The Prostatic Urethral Lift Procedure Using UroLift Implants: Novel, Minimally Invasive Therapy for Benign Prostatic Hyperplasia** *1719*
*Daniel B. Rukstalis*

**149** **Goals and Expectations of Ablation Techniques and Emerging Therapies for Benign Prostatic Hyperplasia: An Editorial** *1727*
*Catriona I. MacRae & Peter J. Gilling*

**150** **Monopolar Transurethral Resection of Prostate** *1733*
*Madhu S. Agrawal & Dilip K. Mishra*

**151** **Ablation of Prostate: Bipolar Resection** *1743*
*Jaspreet S. Sandhu*

**152** **Bipolar Vaporization of the Prostate** *1752*
*Ahmet Karakeci, Kyle Richards, & Gopal H. Badlani*

**153** **Single Port for Prostate Surgery** *1762*
*Rene J. Sotelo, Oscar D. Martín Garzón, Camilo Giedelman, Fatima Z. Husain, & Mihir Desai*

154 **Bladder Injections for Refractory Overactive Bladder: Intra- and Transvesical Procedures** *1775*
*Adam Althaus & Anurag K. Das*

155 **STING Procedure for Reflux** *1784*
*Steve J. Hodges*

156 **Minimally Invasive Therapy for Bladder Pain Syndrome (Interstitial Cystitis)** *1792*
*Ricardo Palmerola, Sandeep Gurram, & Robert Moldwin*

157 **New Techniques for Resecting Bladder Tumors** *1806*
*Alexey G. Martov, Dmitry V. Ergakov, Nikolay A. Baykov, & Zhamshid Okhunov*

158 **Incision: Endoscopic Management of Urethral Stenoses** *1815*
*Gerald H. Jordan & Kurt A. McCammon*

159 **Endoscopic Management of Bladder Neck Contracture Following Radical Prostatectomy** *1826*
*Susan MacDonald, R. Caleb Kovell, Joseph Tortora, & Ryan P. Terlecki*

160 **Single-incision Slings** *1832*
*Michael J. Kennelly & Dina A. Bastawros*

161 **Bioinjectables for Stress Urinary Incontinence** *1847*
*Ryan Dobbs, Simone Crivellaro, & John J. Smith III*

162 **Midurethral Slings for the Treatment of Female Stress Urinary Incontinence** *1854*
*Alice Drain & Victor W. Nitti*

163 **Maxi/Pubovaginal Sling** *1871*
*Gopal H. Badlani & Joao P. Zambon*

164 **Mesh Complications Associated with Vaginal Prolapse Surgery** *1880*
*Jeffrey S. Schachar & G. Willy Davila*

165 **Male Slings for Treatment of Post-prostatectomy Incontinence** *1890*
*Ajay K. Singla & Nirmish Singla*

166 **Neuromodulation** *1902*
*Dayron Rodríguez & Anurag K. Das*

University of Maryland School of Medicine
Hanover, MD, USA

**Omar M. Aboumarzouk, MBChB, MSc, PhD, MRCS(Glasg), FRCS(Urol)**
Consultant Urological Surgeon
Department of Urology
Glasgow Urological Research Unit
Queen Elizabeth University Hospital
Glasgow, UK

**Samuel Abourbih, MDCM**
Assistant Professor of Urology
Loma Linda University Medical Center
Loma Linda, CA, USA

**Cenk Acar, MD**
Associate Professor
Eryaman Hospital
Department of Urology
Ankara, Turkey

**Melanie A. Adamsky, MD**
Urology Resident
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

**Madhu S. Agrawal, MBBS, MS, MCh, MNAMS**
Head
Department of Urology & Center for Minimally Invasive Endourology
Global Rainbow Healthcare
Agra, India

**Rajesh Ahlawat, MS, MCh**
Chairman
Medanta Kidney and Urology Institute
Gurgaon, India

**Hashim U. Ahmed, FRCS(Urol), PhD, BM, BCh, MA**
Chair of Urology & Consultant Urological Surgeon
Division of Surgery
Department of Surgery and Cancer
Faculty of Medicine
Imperial College London;
Imperial Urology
Imperial College Healthcare NHS Trust
London, UK

**Husain Alenezi, MD**
Consultant Urologist
Urology Unit
Department of Surgery
Sabah Al-Ahmad Urology Center and Al-Adan Hospital
Kuwait

**Peter Alken, MD, PhD**
Professor of Urology
Consultant Urologist
Department of Urology
University Clinic Mannheim
Mannheim, Germany

**Adam Althaus, MD**
Resident in Urology
Harvard Longwood Program in Urology
Boston, MA, USA

**Sapan N. Ambani, MD**
Assistant Professor
Department of Urology
University of Michigan Health Systems
Ann Arbor, MI, USA

**Alok A. Anand, MD, DABR, CIIP**
Interventional Radiologist
Chairman and Chief Quality Officer
Department of Radiology – Eastern Connecticut Health Network
Manchester, CT, USA

**Sero Andonian, MD, MSc, FRCSC, FACS**
Associate Professor
Division of Urology
McGill University Health Centre
McGill University
Montreal, QC, Canada

**Gerald L. Andriole, MD**
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

**Judith Aronsohn, MD**
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

**Sohrab Arora, MS, MCh**
Senior Fellow – Robotic Surgery
Vattikuti Urology Institute
Detroit, MI, USA

**Dean G. Assimos, MD**
Anton Bueschen Chairman
Professor of Urology
Department of Urology
University of Alabama at Birmingham
Birmingham, AL, USA

**Riccardo Autorino, MD**
Attending Urologist and Associate Professor of Urology
Division of Urology
McGuire VAMC and
Virginia Commonwealth University
Richmond, VA, USA

**Abimbola Ayangbesan, BA**
Urology Resident
Vanderbilt University Medical Center
Nashville, TN, USA

**Timothy D. Averch, MD, FACS**
Professor
Vice Chair for Quality
Director of Endourology
Division Chief of Urology – UPMC Presbyterian
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

**Gopal H. Badlani, MD, FACS, FRCS (Hon)**
Vice Chair Urology
Professor of Urology and Gynecology
Wake Forest University
Winston-Salem, NC, USA

**Demetrius H. Bagley, MD**
The Nathan Lewis Hatfield
Professor of Urology
Professor of Radiology
Department of Urology
Sidney Kimmel Medical College at
Thomas Jefferson University Hospital
Philadelphia, PA, USA

**Mehar Bains**
Research Intern
USC Institute of Urology
Keck School of Medicine
University of South California
Los Angeles, CA, USA

**Joseph A. Baiocco, BS**
Medical Research Scholar
Urologic Oncology Branch
National Cancer Institute
National Institutes of Health
Bethesda;
Medical Student
Sidney Kimme Medical College
Thomas Jefferson University
Philadelphia, PA, USA

**D. Duane Baldwin, MD**
Professor of Urology
Director of Urologic Research
Loma Linda University Medical Center
Loma Linda, CA, USA

**Edward J. Bass, MBChB (Hons)**
Urology Specialist Registrar
The Division of Surgery and
Interventional Science
University College London
London;
Department of Urology
University College London Hospitals
London, UK

**Dina A. Bastawros, MD**
Fellow
Department of Obstetrics and Gynecology
Female Pelvic Medicine and
Reconstructive Surgery
Atrium Health
Charlotte, NC, USA

**Chad Baxter, MD**
Assistant Professor of Urology
David Geffen School of Medicine at UCLA
Los Angeles, CA, USA

**Nikolay A. Baykov, MD**
Doctor of Urology
Department of Urology
Municipal Hospital No. 57
Moscow, Russia

**John R. Bell, MD**
Assistant Professor
Department of Urology
University of Kentucky
Lexington, KY, USA

**Norberto O. Bernardo, MD**
Professor of Urology
Chief, Endourology
Hospital de Clínicas José de San Martín
Universidad de Buenos Aires
Buenos Aires, Argentina

**Thomas Bessede, MD**
Assistant Professor
Department of Urology
University of Paris-Sud
Orsay, France

**Amul Bhalodi, MD**
Chief Resident
New York Medical College
Department of Urology
Valhalla, NY, USA

**Giampaolo Bianchi, MD**
Full Professor of Urology
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Murat Binbay, MD**
Associate Professor of Urology
Chairman of Urology Department
Department of Urology
Haseki Training and Research Hospital
Istanbul, Turkey

**Vincent G. Bird, MD**
Professor of Urology
Department of Urology
University of Florida
Gainesville, FL, USA

**Jay T. Bishoff, MD**
Director
Intermountain Urological Institute
Intermountain Health Care
Salt Lake City, UT, USA

**Chandra Shekhar Biyani, MS, D Urol, FRCS (Urol), FEBU, MSc**
Consultant in Urology
Department of Urology
St James' University Hospital
Leeds, UK

**Jerry G. Blaivas, MD**
Professor of Urology
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

**Robert C. Blue, MD**
Assistant Professor of Radiology
Department of Radiology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

**Damien M. Bolton, MD, MBBS, BA, FRACS, FRCS**
Professor
Department of Urology
Austin Hospital
Heidelberg;
Olivia Newton-John Cancer Wellness and
Research Institute
Heidelberg, VIC, Australia

**Alberto Breda, MD**
Chief
Uro-Oncology Division and Kidney Transplant Units
Fundació Puigvert
Autonoma University of Barcelona
Barcelona, Spain

**Jeffrey A. Cadeddu, MD**
Professor
Ralph C. Smith, MD, Distinguished Chair in Minimally
Invasive Urologic Surgery
Department of Urology
University of Texas Southwestern Medical Center
Dallas, TX, USA

**David Canes, MD**
Associate Professor of Urology
Tufts University Medical Center;
Institute of Urology
Lahey Hospital & Medical Center
Burlington, MA, USA

**Noah E. Canvasser, MD**
Assistant Instructor
Department of Urology
University of Texas Southwestern
Medical Center
Dallas, TX, USA

**Sam S. Chang, MD, MBA**
Patricia and Rodes Hart Endowed Chair of Urologic Surgery
Professor of Urologic Surgery and Oncology
Department of Urological Surgery
Vanderbilt University Medical Center
Nashville, TN, USA

**Rajeev Chaudhry, MD**
Pediatric Urology Fellow
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, PA, USA

**Raju R. Chelluri, MD, MS**
Urology Resident
Division of Urology
Department of Surgery
University of Pennsylvania
Perelman School of Medicine;
Research Fellow
Urologic Oncology Branch
National Cancer Institute
National Institute of Health
Bethesda, MD, USA

**Marcelo Chen, MD, PhD**
Senior Attending Urologist
Department of Urology
MacKay Memorial Hospital;
Associate Professor
Department of Medicine
MacKay Medical College
Taipei, Taiwan

**Ben H. Chew, MD, MSc, FRCSC**
Associate Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**Sameer Chopra, MD, MS**
Resident Physician
USC Institute of Urology
Keck School of Medicine
University of South California
Los Angeles, CA, USA

**Peter L. Choyke, MD**
Program Director
Molecular Imaging Program
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

**Kai-wen Chuang, MD**
CHOC Children's Urology
Pediatric Urologist
HS Assistant Clinical Professor
Department of Urology
University of California
Irvine, CA, USA

**Bilal Chughtai, MD**
Assistant Professor of Urology
Department of Urology
Weill Cornell Medical College
New York Presbyterian Hospital
New York, NY, USA

**Doreen E. Chung, MD, FRCSC**
Assistant Professor
Department of Urology
Female Pelvic Medicine & Reconstructive Surgery
Columbia University
New York, NY, USA

**Ralph V. Clayman, MD**
Professor of Urology
Department of Urology
University of California
Irvine, CA;
Dean Emeritus
University of California Irvine
School of Medicine
Orange, CA, USA

**Crystal R. Combs, RN, CNOR**
Clinical Education Resource Nurse - Robotics Wake Forest Baptist Health
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

**Marius C. Conradie, MD**
Urologist in Private Practice
President Southern African Endourology Society
Netcare Waterfall City Hospital
Johannesburg, South Africa

**Brett Cox, MD**
Interim Chair
Department of Radiation Medicine
Lenox Hill Hospital;
Chief of Brachytherapy
Northwell Health;
Co-Director
GU Center of Excellence
Northwell Cancer Institute;
Associate Professor of Radiation Medicine

Zucker School of Medicine at Hofstra/Northwell
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

***Cecilia M. Cracco, MD, PhD***
Urologist
Department of Urology
Cottolengo Hospital
Torino, Italy

***Simone Crivellaro, MD***
Assistant Professor of Urology
Department of Urology
University of Illinois at Chicago
Chicago, IL, USA

***Anurag K. Das, MD, FACS***
Director
Center for Neuro-urology and Continence
Division of Urology
Department of Surgery
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA, USA

***Judson D. Davies, MD***
Clinical Assistant Professor of Surgery
Department of Urological Surgery
Vanderbilt University Medical Center
Nashville, TN, USA

***G. Willy Davila, MD***
Chairman
Department of Gynecology
Section of Urogynecology and Reconstructive
Pelvic Surgery
Cleveland Clinic Florida
Weston, FL, USA

***Jose De La Cerda III, MD, MPH***
Urology Resident
Department of Urology
University of Texas Health Science
Center at San Antonio
San Antonio, TX, USA

***Jean de la Rosette, MD, PhD***
Chairman
Professor of Urology
Department of Urology
Istanbul Medipol University
Istanbul, Turkey

***John D. Denstedt, MD, FRCSC, FACS, FCAHS***
Professor of Urology
Division of Urology
Department of Surgery
Schulich School of Medicine & Dentistry
The University of Western Ontario
London, ON, Canada

***Samir Derisavifard, MD***
Resident in Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

***Janak D. Desai, MS, MCh***
Chief of Urology Services
Samved Hospital and Sterling Hospitals
Ahmedabad, India

***Mahesh R. Desai, MS, FRCS, FRCS, FACS***
Medical Director
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

***Mihir Desai, MD***
USC Institute of Urology
Keck School of Medicine
University of Southern California
Los Angeles, CA, USA

***Neil B. Desai, MD, MHS***
Assistant Professor
Department of Radiation Oncology
University of Texas Southwestern Medical Center
Dallas, TX, USA

***Ryan Dobbs, MD***
Urology Resident
Department of Urology
University of Illinois at Chicago
Chicago, IL, USA

***Steeve Doizi, MD, MSc***
Assistant Professor
Sorbonne Université
Department of Urology
GRC n°20
Groupe de Recherche Clinique sur la Lithiase Urinaire
Hôpital Tenon
Paris, France

***Carolyn K. Donaldson, MD***
Associate Professor
Department of Radiology
NorthShore University Health System

University of Chicago
Pritzker School of Medicine
Evanston, IL, USA

***Rodrigo Donalisio da Silva, MD***
Assistant Professor of Surgery/Urology
University of Colorado Denver
Denver Health Medical Center
Denver, CO, USA

***Oonagh Dowling, PhD***
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

Head of Department
Department of Urology
Asklepios Klinik Barmbek
Hamburg, Germany

***Frederick A. Gulmi, MD***
Vice Chairman
Department of Urology
Clinical Associate Professor of Urology
NYU School of Medicine
New York;
Chief of Urology
NYU Langone Hospital-Brooklyn
Brooklyn, NY, USA

***Mantu Gupta, MD***
Chair of Urology
Mount Sinai West
New York;
Professor
Icahn School of Medicine at Mount Sinai
New York;
Director of Endourology
Mount Sinai Health Care System
New York;
Director
Mount Sinai Kidney Stone Center
New York, NY, USA

***Sandeep Gurram, MD***
Resident Physician
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

***Jorge Gutierrez-Aceves, MD***
Professor of Urology
Director of Endourology
Wake Forest University School of Medicine
Department of Urology
Winston-Salem, NC, USA

***Christopher S. Han, MD***
Urology Resident
Division of Urology
Rutgers Robert Wood Johnson Medical School
New Brunswick, NJ, USA

***Misop Han, MD, MS***
David Hall McConnell Professor in Urology and Oncology
James Buchanan Brady Urological Institute
Johns Hopkins School of Medicine
Baltimore, MD, USA

***David M. Hananel, BSc, BA***
Director
Center for Research in Education & Simulation Technologies
University of Washington
School of Medicine
Seattle, WA, USA

***Hendrik Heers, Dr. med***
Senior Endourology Fellow (EBU)
Department of Urology
Nuffield Department of Surgical Sciences
University of Oxford
Oxford, UK

***Douglas K. Held, MD, FACS***
Northwell Health Long Island Jewish Medical Centre
New Hyde Park, NY, USA

***Ashok K. Hemal, MD, MCh, FACS, FRCS***
Professor
Wake Forest Institute for Regenerative Medicine;
Chair, Robotics Committee
Baptist Medical Center;
Fellowship Director
Robotics and Minimally Invasive Surgery;
Fellowship Co-Director
Endourology
Wake Forest Baptist Medical Center and Wake Forest School of Medicine
Winston-Salem, NC, USA

***Derek B. Hennessey, MD, MBBChBAO, BMedSci, DHSM, PDipHS, FRCSI, FEBU***
Fellow
Department of Urology
Austin Hospital
Heidelberg
Olivia Newton-John Cancer Wellness and Research Institute
Heidelberg, VIC, Australia

***S. Duke Herrell, MD, FACS***
Professor of Urologic Surgery, Biomedical and Mechanical Engineering
Vanderbilt University Medical Center
Nashville, TN, USA

**Joel Hillesohn, MD**
Chief Resident
Department of Urology
New York Medical College
New York, NY, USA

**Steve J. Hodges, MD**
Assistant Professor of Pediatric Urology
Pediatric Urology
Institute for Regenerative Medicine
Wake Forest University School of Medicine
Winston-Salem, NC, USA

**David M. Hoenig, MD**
Chief of Urology
Professor
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**R. John D'A. Honey, MA, MB, BChir, FRCS(Eng), FRCSC**
Professor of Surgery
Division of Urology
St. Michael's Hospital
Toronto;
Department of Surgery
University of Toronto
Toronto, ON, Canada

**Adam S. Howe, MD**
Pediatric Urology Fellow
Department of Pediatric Urology
Cohen Children's Medical Center
Zucker School of Medicine at Hofstra/Northwell
Long Island, NY, USA

**Scott G. Hubosky, MD**
The Demetrius H. Bagley, Jr. M.D.
Associate Professor of Urology
Director of Endourology
Vice Chair of Quality and Safety
Department of Urology
Sidney Kimmel Medical College at
Thomas Jefferson University Hospital
Philadelphia, PA, USA

**Amanda P. Hughes, BSN, RN, CNOR**
Clinical Coordinator for Urology
Inpatient Surgical Services
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

**Fatima Z. Husain, MD**
USC Institute of Urology
Keck School of Medicine
University of Southern California
Los Angeles, CA, USA

**Alabdulaali Ibrahim, MD**
Consultant of Urology
Department of Surgery
Prince Mohammed Bin Abdulaziz Hospital
Riyadh, Saudi Arabia

**Johann P. Ingimarsson, MD**
Clinical Assistant Professor
Maine Medical Center and Tufts School of Medicine
Division of Urology
Portland, ME, USA

Resident Physician
Department of Urology
University of Michigan Health System
Ann Arbor, MI, USA

**Wooju Jeong, MD**
Senior Urologist
Vattikuti Urology Institute
Department of Urology
Henry Ford Health System
Detroit, MI, USA

**Ghalib A. Jibara MD, MPH**
Resident Physician in Urology
Department of Surgery
Division of Urology
Duke University Hospital
Durham, NC, USA

**J. Stephen Jones, MD, MBA**
President Cleveland Clinic Regional Hospitals and Family Health Centers
Professor and Horvitz/Miller Distinguished Chair in Urological Oncology
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Tonye A. Jones, MD**
Urology Resident
UCLA Department of Urology
Los Angeles, CA, USA

**Gerald H. Jordan, MD**
Professor Emeritus
Department of Urology
Eastern Virginia Medical School
Norfolk, VA, USA

***Adrian D. Joyce, MS, FRCS(Urol)***
Honorary Consultant in Urology
Department of Urology
St James' University Hospital
Leeds, UK

***Ilan Z. Kafka, MD***
Endourology/Minimally Invasive
Surgery Fellow
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Kamaljot S. Kaler, MD***
Fellow
Department of Urology
University of California
Irvine, CA, USA

***Panagiotis Kallidonis, MD, PhD, FEBU***
Assistant Professor
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

***Wissam Kamal, MD***
Consultant Urological Surgeon
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

***Jihad H. Kaouk***
Cleveland Clinic
Glickman Urological and Kidney Institute
Cleveland, OH, USA

***Adam G. Kaplan, MD***
Fellow in Endourology, Laparoscopy and
Robotic Surgery
Division of Urologic Surgery
Duke University Medical Center
Durham, NC, USA

***Ahmet Karakeci, MD***
Assistant Professor (International Observer)
Department of Urology
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

***Dimitrios Karnabatidis, MD, PhD***
Professor
Department of Radiology
University Hospital of Patras
Rion, Patras, Greece

***Parviz K. Kavoussi, MD, FACS***
Reproductive Urologist
Department of Reproductive Urology
Austin Fertility & Reproductive
Medicine/Westlake IVF;
Adjunct Assistant Professor
Department of Urology
University of Texas Health Sciences
Center at San Antonio
Austin, TX, USA

***Yoshihide Kawasaki, MD***
Assistant Professor
Department of Urology
Tohuku University Graduate School of Medicine
Sendai, Miyagi, Japan

***Francis X. Keeley, Jr., MD, FRCS(Urol)***
Consultant Urologist
Bristol Urological Institute
Bristol, UK

***Michael J. Kennelly, MD, FPMRS, FACS***
Professor
Department of Urology and Gynecology
Women's Center for Pelvic Health
Atrium Health
Charlotte, NC, USA

***Eric H. Kim, MD***
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

***Fernando J. Kim, MD, MBA, FACS***
Professor of Surgery
Division of Urology
Urology-Denver;
Chief of Urology
Denver Health Medical Center
Denver, CO, USA

***Hidefumi Kinoshita, MD, PhD***
Professor
Department of Urology and Andrology
Kansai Medical University Hospital
Hirakata, Osaka, Japan

***John J. Knoedler, MD***
Assistant Professor of Surgery
Division of Urology
Penn State Milton S. Hershey
Medical Center
Hershey, PA, USA

**Bodo E. Knudsen, MD, FRCSC**
Associate Professor
Department of Urology
The Ohio State University Wexner Medical Center
Columbus, OH, USA

**Dimitrios Kotsiris, MD**
Urology Specialist
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

**R. Caleb Kovell, MD**
Assistant Professor of Clinical Urology in Surgery
Department of Urology
University of Pennsylvania
Philadelphia, PA, USA

**Amy E. Krambeck, MD**
Michael O. Koch Professor of Urology
Department of Urology
Indiana University
Indianapolis, IN, USA

**Jessica E. Kreshover, MD, MS**
Assistant Professor of Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**M. Pilar Laguna, MD, PhD**
Professor of Uro-oncology
Department of Urology
AMC University of Amsterdam
Amsterdam, The Netherlands

**Weil R. Lai, MD**
Clinical Instructor
Fellow
Department of Urology
Tulane University School of Medicine
New Orleans, LA, USA

**Win Shun Lai, MD**
Resident
Department of Urology
University of Alabama at Birmingham
Birmingham, AL, USA

**Michael Lam, MD**
Resident in Urology
Department of Urology
Oregon Health and Science University
Portland, OR, USA

**Daniel J. Lama, MD**
Resident
Division of Urology
University of Cincinnati School of Medicine
Cincinnati, OH, USA

**Jaime Landman, MD**
Professor
Chair
Department of Urology
University of California
Irvine, CA, USA

**Dirk Lange, PhD**
Associate Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**David A. Leavitt, MD**
Associate Director of Endourology
Director of Laser Surgery
Vattikuti Urology Institute
Henry Ford Health System
Detroit, MI, USA

**Amir H. Lebastchi, MD**
Chief Resident
Department of Urology
University of Michigan Health System
Ann Arbor, MI, USA

**Benjamin R. Lee, MD, FACS**
Professor
Chief
Division of Urology
University of Arizona College of Medicine
Tucson, AZ, USA

**Lucille Lee, MD**
Assistant Professor of Radiation Medicine
Zucker School of Medicine at Hofstra/Northwell
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

**Evangelos Liatsikos, MD, PhD**
Professor
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

***Estevao Lima, MD, FEBU, PhD***
Director of CUF Urology Department
Portugal and Department of Urology of Braga Hospital;
Professor of Physiology and Urology
Life and Health Sciences Research Institute
Braga;
ICVS/3B's – Associate Lab. Guimarães
Braga;
School of Medicine
University of Minho
Braga, Portugal

***James E. Lingeman, MD, FACS***
Professor of Urology
Department of Urology
Indiana University School of Medicine
Indianapolis, IN, USA

***Richard E. Link, MD, PhD***
Carlton-Smith Endowed Chair in Urologic Education
Associate Professor of Urology
Director
Division of Endourology and Minimally Invasive Surgery
Scott Department of Urology
Baylor College of Medicine Medical Center
Houston, TX, USA

***Michael E. Lipkin, MD***
Associate Professor in Urology
Department of Surgery
Division of Urology
Duke University Medical Center
Durham, NC, USA

***Igor Lobko, MD***
Chief
Division of Vascular and Interventional Radiology
Director
Vascular and Interventional Radiology Fellowship
Department of Radiology
Long Island Jewish Medical Center
New Hyde Park, NY, USA

***Susan MacDonald, MD***
Assistant Professor of Surgery
Division of Urology
Penn State Milton S. Hershey Medical Center
Hershey, PA, USA

***Catriona I. MacRae, MBBS, BSc***
Registrar
Department of Urology
Tauranga Hospital
Tauranga, New Zealand

***Marc D. Manganiello, MD***
Assistant Professor of Urology
Tufts School of Medicine
Lahey Hospital and Medical Center
Boston, MA, USA

***Robert Marcovich, MD***
Associate Professor and Director of Endourology
Department of Urology
University of Miami Miller School of Medicine
Miami, FL, USA

***Leonard S. Marks, MD***
Professor of Urology
UCLA Department of Urology
Los Angeles, CA, USA

***Eugenio Martorana, MD***
Urology Resident
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

***Alexey G. Martov, MD, PhD, Honored Doctor of Russia***
Professor
Chairman
Department of Urology
Federal Medico-biology Agency;
Professor of Urology
Russian Medical Academy of Postgraduate
Education;
Head of Urology Department
Moscow City Hospital No. 57
Moscow, Russia

***Mahir Maruf, MD***
Research Volunteer
Urologic Oncology Branch
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

***Thomas Masterson, MD***
Resident
Department of Urology
University of Miami Miller School of
Medicine/Jackson Memorial Hospital
Miami, FL, USA

***Brian R. Matlaga, MD, MPH***
The Stephens Professor
James Buchanan Brady Urological Institute
Johns Hopkins University School of Medicine
Baltimore, MD, USA

***Tadashi Matsuda, MD, PhD***
Professor
Chairman
Department of Urology and Andrology
Kansai Medical University
Hirakata, Osaka, Japan

***Matthew J. Maurice, MD***
Clinical Fellow
Cleveland Clinic
Glickman Urological and Kidney Institute
Cleveland, OH, USA

***Kurt A. McCammon, MD***
Professor
Chairman
Department of Urology
Eastern Virginia Medical School
Norfolk, VA, USA

***Mani Menon, MD***
Chairman
Vattikuti Urological Institute
Detroit, MI, USA

***Salvatore Micali, MD***
Associate Professor of Urology
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

***Maurice-Stephan Michel, MD***
Full Professor of Urology
Head of Department of Urology
University Medical Centre Mannheim
Heidelberg University
Heidelberg, Germany

***Arkadiusz Miernik MD, PhD, FEBU***
Associate Professor of Urology
Head of Division of Urotechnology
University of Freiburg – Medical Centre
Department of Urology
Freiburg, Germany

***Brian J. Miles, MD***
Professor of Urology
Weill Cornell Medical College
Medical Director of Robotic Surgery
Houston Methodist Hospital
Houston, TX, USA

***Nicole L. Miller, MD***
Associate Professor
Department of Urology
Vanderbilt University Medical Center
Nashville, TN, USA

***Massimo Mischi, PhD, MSc***
Professor of Biomedical Signal Analysis
Director of Biomedical Diagnostics Labs
Department of Electrical Engineering
Eindhoven University of Technology
Eindhoven
Noord-Brabant
The Netherlands

***Dilip K. Mishra, MBBS, MS, MRCS, MCh***
Consultant Urologist
Department of Urology & Center for Minimally
Invasive Endourology
Global Rainbow Healthcare
Agra, India

***Shashikant Mishra, MS, DNB(Urol)***
Consultant Urologist
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

***Akira Miyajima, MD***
Professor and Chairman
Department of Urology
Tokai University School of Medicine
Isehara, Kanagawa, Japan

***Anthony D. Mohabir, MD***
Consultant Urology
Division of Vascular and Interventional
Radiology
Department of Radiology
Long Island Jewish Medical Center
New Hyde Park, NY, USA

***Robert Moldwin, MD***
Director of Pelvic Pain Treatment Center
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

***Manoj Monga, MD***
Professor of Surgery/Urology
Director of the Stevan Streem Center of
Endourology & Stone Disease
Center of Endourology and Stone Disease
The Cleveland Clinic
Cleveland, OH, USA

**Bradley A. Morganstern, MD**
Assistant Professor of Pediatric Urology
Chief, Pediatric Urology at Children's Hospital of Georgia
Medical College of Georgia
Augusta University
Augusta, GA, USA

**Piruz Motamedinia, MD**
Assistant Professor
Department of Urology
Yale University
New Haven, CT, USA

**Ravi Munver, MD, FACS**
Professor
Vice Chairman
Department of Urology
Hackensack University Medical Center
Hackensack, NJ, USA

**Stephen Y. Nakada, MD, FACS**
Professor
Chairman
The David T. Uehling Chair of Urology
Departments of Urology, Radiology and Medicine
University of Wisconsin School of Medicine and Public Health;
Chief of Service
Department of Urology
UW Health
Madison, WI, USA

**Shyam Natarajan, PhD**
Adjunct Assistant Professor
Department of Urology and Bioengineering
University of California
Los Angeles, CA, USA

**Oktay Nazli, MD**
Professor
Department of Urology
School of Medicine
Ege University
İzmir, Turkey

**Andreas Neisius, MD**
Associate Professor of Urology
Department of Urology
Brüderkrankenhaus Trier
Johannes Gutenberg University
Mainz, Germany

**Christopher Netsch, MD, FEBU**
Assistant Professor of Urology
Fellow in Endourology
Consultant
Department of Urology
Asklepios Klinik Barmbek
Hamburg, Germany

**Naren Nimmagadda, MD**
Resident Physician
Department of Urology
Massachusetts General Hospital
Boston, MA, USA

**Victor W. Nitti, MD**
Professor of Urology and Obstetrics and Gynecology
Vice Chairman
Department of Urology;
Director
Female Pelvic Medicine and Reconstructive Surgery
Department of Urology
New York University Langone Medical Center
New York, NY, USA

**Charles U. Nottingham, MD**
Resident Physician
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

**Yasser A. Noureldin, MD, MSc, PhD**
Lecturer
Department of Urology
Benha Faculty of Medicine
Benha University
Benha, Egypt

**Yaw A. Nyame, MD, MBA**
Resident
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Zeph Okeke, MD**
Associate Professor
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Zhamshid Okhunov, MD**
Endourology Fellow
Department of Urology
University of California
Irvine, CA, USA

**Carol Olsen, MSN, RN, CURN**
Director
System, Urology Clinical Services
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Michael C. Ost, MD**
Chief
Division of Pediatric Urology
Children's Hospital of Pittsburgh of UPMC;
Associate Professor
University of Pittsburgh School of Medicine;
Vice Chairman
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

**Kenneth T. Pace, MD, MSc, FRCSC**
Vice Chief of Surgery
Head, Division of Urology
Researcher, Keenan Research Centre
Li Ka Shing Knowledge Institute
St. Michael's Hospital;
Associate Professor
Department of Surgery
University of Toronto
Toronto, ON, Canada

**Greg Palleschi, MD**
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

**Lane S. Palmer, MD**
Professor of Urology and Pediatrics
Chief, Division of Pediatric Urology
Cohen Children's Medical Center of New York
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Ricardo Palmerola, MD**
Fellow, Female Pelvic Medicine and
Reconstructive Surgery
New York University Langone Medical Center
New York, NY, USA

**Shu Pan, MD**
Resident
Department of Urology
Yale University
New Haven, CT, USA

**Anup Patel, BSc, MBBS, FRCS, MS, FRCS(Urol)**
Consultant Urological Surgeon
London, UK

**Manish N. Patel, MD**
Fellow in Endourology
Wake Forest University School of Medicine
Department of Urology
Winston-Salem, NC, USA

**Roshan Patel, MD**
Endourology Fellow
Department of Urology
University of California
Irvine, CA, USA

**Ryan F. Paterson, MD, FRCSC**
Assistant Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**Margaret S. Pearle, MD, PhD**
Professor
Vice-Chair
Department of Urology
University of Texas Southwestern Medical Center
Dallas, TX, USA

**Renato N. Pedro, MD, PhD**
Lithotripsy Center Coordinator – AME/SBO
UNICAMP;
Professor of Urology
Faculdade de Medicina São Leopoldo Mandic
Campinas, Brazil

**Aleš Petřík, MD, PhD**
Assistant Professor
Department of Urology
Hospital Ceske Budejovice
Ceske Budejovice;
Charles University,
1st Faculty of Medicine
Prague, Czech Republic

**John Phillips, MD, FACS**
Residency Program Director
New York Medical College

Department of Urology
Valhalla, NY, USA

**Giovannalberto Pini, MD**
Urologist
Laparoscopy & Robotic Section
Department of Urology
San Raffaele Turro Hospital
Milan, Italy

**Peter A. Pinto, MD**
Urologic Oncology Branch
National Cancer Institute
National Institute of Health
Bethesda, MD, USA

**Giacomo Maria Pirola, MD**
Urology Resident
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Thomas J. Polascik, MD, FACS**
Professor of Surgery
Director, Urologic Oncology Fellowship
Director, GU program on Focal Therapy
Duke Comprehensive Cancer Center
Duke Cancer Institute
Duke University
Durham, NC, USA

**James R. Porter, MD**
Director, Robotic Surgery
Providence Health and Services
Swedish Urology Group
Seattle, WA, USA

**Louis Potters, MD, FACR, FASTRO**
Professor
Chairperson
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

**Glenn M. Preminger, MD**
James F. Glenn Professor of Urology and Chief
Division of Urology
Department of Surgery
Duke University Medical Center
Durham, NC, USA

**Ali Abdel Raheem, MD, PhD**
Consultant of Uro-oncology
Minimally Invasive Urological Surgery Unit
Tanta University Hospital
Tanta, Arab Republic of Egypt

**Arun Rai, MD**
Resident
Scott Department of Urology
Baylor College of Medicine
Houston, TX, USA

**Soroush Rais-Bahrami, MD**
Assistant Professor of Urology and Radiology
Director, UAB Program for Personalized
Prostate Cancer Care
Departments of Urology and Radiology
University of Alabama at Birmingham
Birmingham, AL, USA

**Rajan Ramanathan, MD**
Professor of Surgery
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Daniel Ramirez, MD**
Urology Associates of Nashville
Nashville, TN, USA

**Dima Raskolnikov, MD**
Resident
Department of Urology
University of Washington
Seattle, WA, USA

**Jens Rassweiler, MD, FRCS(Glasg)**
Professor of Urology
Head of Department of Urology
SLK Kliniken Heilbronn
University of Heidelberg
Heidelberg, Germany

**Marie-Claire Rassweiler-Seyfried, MD, FEBU**
Consultant of Urology
Department of Urology
University Medical Centre Mannheim
Mannheim, Germany

**Ardeshir R. Rastinehad, DO, FACOS**
Associate Professor of Urology
and Radiology
Director of Focal Therapy and Interventional
Urologic Oncology
Department of Radiology and Urology

Icahn School of Medicine at Mount Sinai
New York, NY, USA

***A. Andrew Ray, MD, MSc, FRCSC***
Adjunct Lecturer
University of Toronto
Royal Victoria Regional Hospital
Barrie, ON, Canada

***Hassan Razvi, MD, FRCSC***
Professor
Chair
Division of Urology
Schulich School of Medicine and Dentistry
Western University
London, ON, Canada

***Christopher R. Reynolds***
Fellow
Robotics and Minimally Invasive Surgery
Wake Forest Baptist Medical Center and Wake Forest School of Medicine
Winston-Salem, NC, USA

***Koon Ho Rha, MD, FACS, PhD***
Professor of Urology
Department of Urology
Severance Hospital
Yonsei University College of Medicine
Seoul, South Korea

***Kyle A. Richards, MD, FACS***
Assistant Professor
Department of Urology
University of Wisconsin-Madison
Madison, WI, USA

***Lee Richstone, MD***
Chief of Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

***Manuel Ritter, MD***
Associate Professor
Department of Urology
University Medical Centre Mannheim
Heidelberg University
Heidelberg, Germany

***Pedro L. Rodrigues***
Life and Health Sciences Research Institute
ICVS/3B's - Associate Lab. Guimarães
Braga;
2Ai – Polytechnic Institute of Cávado and Ave
Barcelos, Portugal

***Dayron Rodríguez, MD, MPH***
Resident in Urology
Harvard Massachusetts General Hospital
Program in Urology
Boston, MA, USA

***Craig G. Rogers, MD***
Director of Renal Surgery
Vattikuti Urology Institute
Henry Ford Hospital
Detroit, MI, USA

***Daniel Rosen, MD***
Resident
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

***Ornob Roy, MD***
Assistant Professor of Urology
Carolinas Medical Center
Charlotte, NC, USA

***Daniel B. Rukstalis, MD***
Professor
Department of Urology
Wake Forest University School of Medicine
Winston-Salem, NC, USA

***Matthew P. Rutman, MD***
Associate Professor of Urology at CUMC
Director of Voiding Dysfunction and Female Urology
Columbia University
New York, NY, USA

***Ravindra B. Sabnis, MS, MCH***
Chairman
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

***Simpa S. Salami, MD, MPH***
Assistant Professor
Department of Urology
University of Michigan
Ann Arbor, MI, USA

***Francisco J.B. Sampaio, MD, PhD***
Full Professor and Chairman
Urogenital Research Unit

State University of Rio de Janeiro;
National Council for Scientific and Technological Development – CNPq
Rio de Janeiro, Brazil

**Jaspreet S. Sandhu, MD**
Associate Attending Urologist
Department of Surgery
Urology Service
Memorial Sloan Kettering Cancer Center
New York, NY, USA

**Jeffrey S. Schachar, MD**
Fellow
Female Pelvic Medicine and Reconstructive Surgery
Cleveland Clinic Florida
Weston, FL, USA

**Douglas S. Scherr, MD**
Ronald Stanton Clinical Scholar in Urology
Professor of Urology
Clinical Director, Urologic Oncology
Weill Cornell Medicine
New York Presbyterian Hospital
New York, NY, USA

**John R. Schwabe, MD**
Resident Physician
Wayne State University Department of Urology
Detroit, MI, USA

**Zeyad Schwen, MD**
Resident
James Buchanan Brady Urological Institute
Johns Hopkins School of Medicine
Baltimore, MD, USA

**Cesare M. Scoffone, MD**
Head of the Department of Urology
Cottolengo Hospital
Torino, Italy

**Michelle Jo Semins, MD**
Assistant Professor
Department of Urology
University of Pittsburgh School of Medicine
Pittsburgh, PA, USA

**Ojas Shah, MD**
George F. Cahill Professor of Urology
Director
Division of Endourology and Stone Disease
Department of Urology
Columbia University Irving Medical Center
Columbia University College of Physicians and Surgeons
New York, NY, USA

**Paras H. Shah, MD**
Urologist
Department of Urology
Mayo Clinic
Rochester, MN, USA

**John M. Shields, MD**
Adjunct Clinical Post Doctorate
Minimally Invasive Surgery and Endourology Fellow
Department of Urology
University of Florida
Gainesville, FL, USA

**Pratik A. Shukla, MD**
Radiology Resident
Division of Vascular and Interventional Radiology
Department of Radiology
Mount Sinai Beth Israel
New York, NY, USA

**David N. Siegel, MD, FSIR**
Interventional Radiologist
Vice Chairman, Clinical Affairs-LIJMC
Department of Radiology- Northwell Health
Associate Professor of Radiology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

**Mark V. Silva, MD**
Resident
Department of Urology
Columbia University Irving Medical Center/
NewYork-Presbyterian Hospital
Columbia University College of Physicians and Surgeons
New York, NY, USA

University of Washington
Seattle, WA, USA

***Pei Zhong, PhD***
Professor
Department of Mechanical Engineering and
Materials Science
Duke University
Durham, NC, USA

## Foreword

"Endourology" was the 1978 branding brainchild of Elwin Fraley, Arthur Smith, and Paul Lange.[1] Most felt that the Minnesota cold had finally gone beyond their woolen headgear to create a "brain freeze" of monumental proportions. Fast forward nearly 40 years and, today, endourology has become urology. Diagnostically, from the urethral meatus to the uppermost renal calyx, the entire urogenital tract can be revealed in great detail using both endoscopic and sophisticated imaging technologies. Therapeutically, urologists of talent, innovation, and persistence have supplanted standard incisional access with an endoscopic, image-guided, or combined approach.

If you are reading this Foreword then you are reading a book that contains every aspect of urology and how it is benefited by a minimally invasive (i.e. percutaneous, ureteroscopic, laparoscopic, robotic) or noninvasive image-guided (i.e. shock-wave lithotripsy, focal therapy) approach. The authors are an international *Who's Who* of experts in endourology. The content ranges from basic to futuristic endourology. In 166 chapters, the latest advances in antegrade and retrograde endoscopic nephrostomy, laparoendoscopic single-site surgery, and robotic procedures as well the newest image-guided therapies are clearly detailed and illustrated both in photographs and often by instructional video demonstrations.

A wise mentor[2] once advised me: "You are only as good as tomorrow." That single sentence should haunt each of us as we arise every morning to provide relief to those who suffer. To that end, we must seek methods to relieve suffering rather than cause it, to heal without harming, to cure without substituting one malady for another. Endourology empowers each of us to provide all individuals seeking our care with a kinder, gentler solution to their urological problems. In the first part of the twentieth century, Sir William Osler opined: "Diseases that harm require treatments that harm less."[3] A century later, his dictum has been largely realized in the practice of endourology.

My heartfelt congratulations go out to Drs Smith, Badlani, Kavoussi, Preminger, and Rastinehad, who have provided a comprehensive guide of immense value to me, to you, and to all of our patients. Read *Smith's Textbook of Endourology* well, apply its principles earnestly, and, if opportunity presents, seek to further innovate and build on its contents. The text is not an end in and of itself; rather, it is another paver in the surgical journey in which each of us plays a role — using techniques borne of today's technology to proceed to further reduce the burden of the "surgical" cure we are obligated to apply.

# Preface

The cover of this textbook synthesizes the concepts of endourology. In order to perform endoscopic surgery one needs access to the organ and various forms of energy to facilitate access, control bleeding, and obliterate tissues. These goals can only be accomplished with appropriate devices. Fortunately, evolving technology allows the manufacture of improved devices. It is essential for endourologists to keep abreast of these advances. The fourth edition of this book accomplishes this with an update of the existing chapters by the original authors or complete revision by new authors.

In 1978 the concept of endourology was launched. It was defined as closed, controlled manipulation within the urinary tract. The word "closed" was used to indicate either a minimal incision or no incision at all and the control was achieved either endoscopically or by noninvasive imaging. Until then, residents had been taught that the only way to have good exposure was through a large incision. Now the ultimate goal is good exposure with no incision at all. This is achieved by utilizing a combination of endoscopy and the new modalities of imaging. There are now relatively few accepted open urological procedures and this has had the gratifying result of a dramatic decrease in the morbidity of our patients undergoing treatment.

In this era of fewer working hours for residents, the amount of time that the residents spend in the operating room has decreased dramatically and the necessary skills have to be taught using a combination of additional educational modalities. In addition to books and journals, there are an abundance of videos on surgical techniques, animal laboratories, teaching models, and virtual reality simulators. Fortunately, endourologic techniques are uniquely suited to these modalities and the student can become quite adept by using them before being instructed in the operating room.

As the technology has evolved, courses have been organized by the Endourology Society to train not only the residents and fellows, but also the practicing urologist so that their "learning curve" can be accelerated, and they can then use these techniques with the required expertise. In addition, the Endourology Society has developed the *Journal of Endourology* and the *Journal of Endourology Case Reports* to update urologists on the latest technology. The *Journal of Endourology* allows the members access the *Journal of Videourology* which features videos of new and established techniques on the computer or tablet.

This textbook consists of two volumes. Volume 1 is on stones of the upper tract. Volume 2 is on robotic and laparoscopic surgery and image-guided diagnostic and therapeutic techniques together with minimally invasive therapy of the lower urinary tract. Volume 1 consists of five sections. Section 1 discusses the basic principles. Section 2 is devoted to percutaneous renal surgery. Section 3 discusses the intricacies of ureteroscopy. Section 4 is on shock-wave lithotripsy. We are cognizant of the fact that there is no single modality for the treatment of stones and hence Section 5 describes the management of the patient with various stone-related problems in a composite format.

Volume 2 covers robotic and laparoscopic surgery. At present, there is very little difference between the techniques and that which there is is primarily related to technical experience, availability of the robot, and financial considerations. Sections 6 and 7 discuss image-guided diagnostics and therapeutics. This is an important addition to our *Textbook of Endourology*, as it is an essential component of the armamentarium of the practicing urologist, particularly as we move into the era of "no incision." If the procedures described in this section are not performed by urologists, then they will be taken over by radiologists. This in turn will result in the loss of continuity of care of our patients.

I would like to thank each of the contributors for the many hours they have devoted to writing, illustrating, and creating videos for their chapters. Hopefully, they will be as delighted with the results as the editors and publishers of this textbook. I am also deeply indebted to my co-editors, who have reviewed, edited, and re-reviewed chapters countless times. Thanks to their families as well, as the time spent on the book could have been devoted to them. The staff at Wiley Blackwell and the project manager Mirjana Misina have been highly professional and encouraging. When one deals with a large organization, it is reassuring to know that as a book bounces from one stage to the next there has been a "continuity of care throughout the operation." They are a great team and we appreciate all the help we received from them.

Finally, I would like to thank my wife, Kay, who inspired me to edit this fourth edition and has repeatedly helped me with this and countless other projects throughout my academic career. If I am regarded as the "father" of endourology, she is unquestionably the "mother" who has helped to nurture this field of urology.

June 2018 *Arthur D. Smith*

## About the Companion Website

This book is accompanied by a companion website:

**www.wiley.com/go/smith/textbookofendourology**

The website includes:

- Over 100 videos showing procedures as described in the book
- PowerPoints of all figures from the book for downloading

All videos are referenced in the text where you see this icon: 👁

# Care and Sterilization of Instruments

*Carol Olsen*

*The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## History of sterilization

The creation and use of surgical instruments has occurred since prehistoric times. The effects of using instruments that were neither clean nor sterile were not a major concern in past eras. The methods for the care and sterilization of instruments have gone through a huge change and have greatly improved over the last few centuries. It was not until the nineteenth century that the development and recognition of a process for instrument sterilization occurred. During this time the focus on the need to sterilize instruments prior to a surgical procedure developed from the effects of post-surgery wound management and the need to eliminate the increased infections of these wounds. This recognition led to the evolution and development of the current standard practice of instrument sterilization.

Noted in the nineteenth century, surgeons performed operations in their street clothes, which were often dirty, and they also reused instruments without a standard cleaning process. In 1864, Joseph Lister introduced the use of phenol, or carbolic acid, on inanimate objects and surfaces as well as human tissue, in hospital wards and operating rooms which resulted in a dramatic decrease in the incidence of wound infections. The carbolic acid was used in conjunction with other components to dress wounds in an antiseptic manner which prevented bacteria from entering the wound. This led Lister to introduce other methods of asepsis, such as sterilization of surgical instruments by applying heat and carbolic acid and the frequent cleaning of the surgeon's hands during an operation. After publication of these findings, in the *The Lancet* in 1867 the "era of antiseptic surgery" was introduced into the field of medicine and surgery. By the year 1875 Lister's principles of antiseptic surgery were accepted worldwide [1].

The steam autoclave was derived from a steam digester currently known as a pressure cooker invented by a physicist named Denis Papin in the late 1600s. By 1879, Charles Chamberland, a colleague of Louis Pasteur, made improvements to Papin's invention and invented a porcelain dish with tiny holes that was able to filter microorganisms from liquid that was poured through this dish. This is known as the Chamberland filter or the Chamberland–Pasteur filter and with his further research in 1884 the autoclave was invented. The use of pressurized steam sterilization of instruments with an autoclave was introduced by Ernst von Bergmann in 1886.

Ethylene oxide (ETO) was first used in 1938 to preserve spices. In the 1950s, ETO was accepted by the medical device industry as a sterilant after a US army researcher investigated the microbicidal effect of ETO and published his findings [2]. This method of sterilization has been used for heat-sensitive instruments, such as flexible scopes and lenses. In the early 1900s, urological instruments were sterilized in a formalin sterilizer and disinfected with a carbolic acid solution. The formalin sterilizer exposed instruments to heated formalin vapors for 2 hours and remained in the sterilizer until use [3].

Since the late 1980s other methods of sterilization were developed that were less caustic to instruments, required less process time, are noncarcinogenic, and allowed for sterile instrument availability. These methods have replaced some of the older sterilization methods.

## Instrument processing

Any item, such as an instrument or medical device that is intended to be reused in a sterile procedure, must be processed in a specific manner, beginning with cleaning and ending with sterilization or high-level disinfection (HLD).

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

In order for sterilization or HLD of an item to be effective, the following steps must occur in a proper and adequate manner: precleaning, cleaning, decontamination, rinsing, drying, disinfection (includes HLD immersion and rinsing with sterile water) or sterilization, and storage. The necessary type of package or container preparation the item will be placed in is determined by the method of sterilization, such as a paper peel package or metal container. In some instances the item may be placed in storage until reuse, such as those that require, at the minimum, HLD.

Urologic instruments consist of reusable flexible cystoscopes, flexible ureteroscopes, flexing instruments for endoscopes, rigid cystoscopes, semi-rigid ureteroscopes, transurethral resection instruments, rigid nephroscopes, laparoscopic instruments, metal dilators, various metal surgical instruments, and ultrasound probes, both external and internal (intracavity, endorectal, or prostate biopsy probes).

First the item should be categorized to determine which type of disinfection or sterilization method is recommended for processing. In 1968 Earl H. Spaulding categorized medical instruments and items used for patient care as critical, semicritical, and noncritical based on the degree of risk for infection with the processing and reuse of each item. These categories make up the Spaulding scheme or Spaulding classification system, which is a recognized resource when describing the appropriate disinfection and sterilization process for medical instruments and devices [4, 5]. Critical items are instruments which will come in direct contact with sterile tissue, enter the vascular system, or penetrate the skin. They require sterilization by such methods as steam, ETO, hydrogen peroxide gas plasma, or a liquid chemical sterilant such as peracetic acid [6]. Semicritical items are instruments which will come in contact with mucous membranes and require sterilization or at a minimum HLD. These items have been identified as high risk for transmitting infection [7]. Noncritical items are instruments or medical devices, such as a stethoscope or blood pressure cuff, which will come into contact with intact skin only and require intermediate to low-level disinfection, such as an impregnated antimicrobial wipe. Neglect of low-level disinfection can lead to cross-contamination to the healthcare worker's hands; reuse of the instrument or medical device with another patient also causes cross-contamination [5, 8–10].

Utilization of a reusable instrument or medical device is a major risk due to the potential introduction of pathogenic microorganisms, which can lead to infection. Therefore, adequate cleaning is imperative to successfully eliminate the bioburden or microbes present on an instrument. Cleaning and decontamination of any level of item used in any type of healthcare facility is a mandatory requirement prior to reuse. Each facility must have a policy and procedure manual in place which identifies the process of cleaning or decontamination, followed by the process for disinfection or sterilization of these items when indicated.

Cleaning is the most important step in the process leading to sterilization or HLD and begins with physically removing microbes in preparation for the next step, which is decontamination [8]. There are different accepted methods for cleaning instruments prior to disinfection or sterilization. These are either manual or automated, which can include a washer/sterilizer, ultrasonic cleaner, or washer/decontaminator [11].

Prior to the cleaning process, any healthcare personnel must don personal protective equipment (PPE) to protect their eyes, skin, and clothing from splashing or droplet contact from any angle [12]. PPE includes eye protection (goggles or mask with shield), mask, impervious gown with long sleeves, gloves, hair bonnet or cap, and shoe covers to avoid exposure to microorganisms and for personal safety protection [6, 11]. After the cleaning and decontamination process, the PPE must be removed or doffed followed by hand hygiene practice [12].

Manual cleaning involves three components: a low-sudsing detergent or enzymatic cleaner, a brush or sponge, and friction [13]. These components will ensure the removal of tissue and debris from an instrument. Manual cleaning of an item begins with immersion in a receptacle or deep sink filled with detergent or enzyme cleaner and warm water solution. Preparation of the detergent or enzymatic cleaner must follow the manufacturer's instructions to ensure the solution is the correct concentration and temperature to maintain its effectiveness. Many cleaners are designed with a premeasuring pump mechanism; healthcare personnel must make certain a full depression of the pump occurs to ensure appropriate solution concentration. A weak solution may fail to break down proteinaceous tissue or a strong solution may create sudsy bubbles which form air pockets and can prevent surface contact by the cleaner. To accurately fill the receptacle or sink with the correct amount of water, a fluid depth indicator or line should be placed for guidance of accuracy [13, 14]. An example is shown in Figure 1.1. A visible instruction guide should indicate the correct solution amount to be added to the correct measurement of water; for example 1 ounce of detergent to 1 gallon of water (Figure 1.2). To prevent aerosol formation by microorganisms, the item being cleaned should be kept immersed below the solution level [8].

Prior to immersion, if the item has numerous parts it must be disassembled, and hinged instruments must be kept in the open, unlocked position. Gentle scrubbing of the item with a soft-bristle brush or sponge will assist in

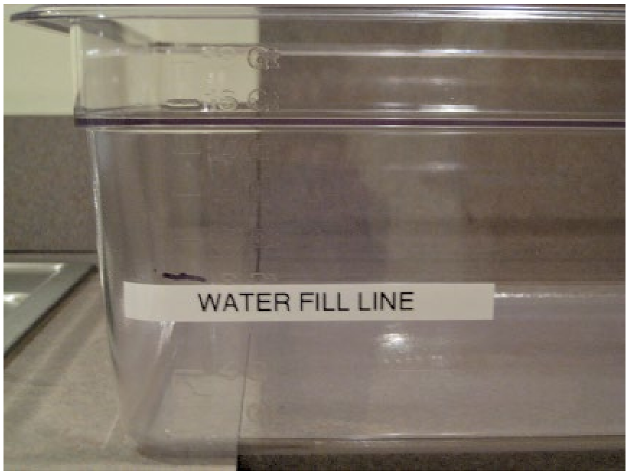

**Figure 1.1** Example of the fill line of a cleaning receptacle.

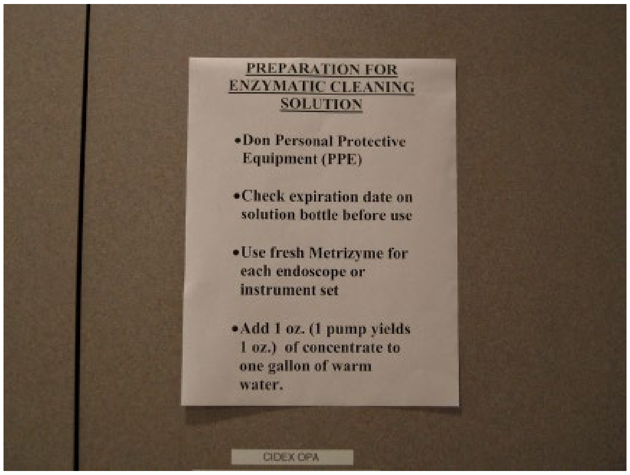

PREPARATION FOR ENZYMATIC CLEANING SOLUTION

- Don Personal Protective Equipment (PPE)
- Check expiration date on solution bottle before use
- Use fresh Metrizyme for each endoscope or instrument set
- Add 1 oz. (1 pump yields 1 oz.) of concentrate to one gallon of warm water.

**Figure 1.2** Visible instructions for preparing an enzymatic cleaner.

removal of bioburden and preservation of the instrument's functions and effectiveness [11]. The most recent recommendation is to use a disposable, single-use brush or sponge. The use of disposable brushes or sponges during the cleaning process will help to prevent cross-contamination to instruments, endoscopes, and medical devices. If a reusable brush is to be used due to cost issues then it must follow undergo HLD between each use [6]. Endoscope manufacturers each have their own select line of various styles and sizes of single-use brushes, with instructions for use (IFU) guidelines for their specific endoscope models. The correct brush should be used for each instrument; the important components of the brush when selecting which one to use are its length, diameter, design, and material [15]. For example, the proper brush used for a flexible cystoscope should be longer than the scope itself, be the right diameter to easily fit through the internal working channels, be kink-resistant, and have a plastic tip on the end to protect the scope internal channel(s).

The next step in manual cleaning is to thoroughly rinse the item with cool tap water in a deep sink to allow for ample movement. Following rinsing, sufficient drying time is needed before the item is to be prepared for sterilization or HLD.

In urology, endoscopes, both flexible and rigid, are a frequently used. They are valuable diagnostic tools that are reusable and require healthcare personnel to follow the guidelines for reprocessing to prevent an outbreak of infection due to improper cleaning. These scopes are introduced into the bladder to examine its appearance and anatomy, as well as the lower urinary tract and prostate gland. Other uses are for urine specimen collection, bladder biopsies, removal of small stones, small foreign objects, or an indwelling ureteral stent. An estimated 4 million or more cystoscopies are performed in the United States each year [16].

When indicated by the manufacturer a leak test should be performed on flexible endoscopes after precleaning and prior to full immersion of the scope in the cleaning solution. This test is done to check the integrity of the outer covering and the internal lining of the scope shaft for any leaks. Before the shaft of the scope is submerged in water, the scope manufacturer leak testing device (which may be manual/hand-operated or automated) is connected to the flexible scope to allow pressurized air to fill the internal channel. The purpose of this test is to determine if there are any microscopic holes from continued use and reprocessing, which would be a source of contamination due to fluid accumulation. The presence of a leak will be identified if the pressurized scope produces a flow of bubbles when inserted in water. Careful inspection of the flexible endoscope for any visible cracks, tears in the sheath material, or malfunctions of its performance is another vital step in reprocessing [6, 7].

External surfaces should be washed with a soft brush or sponge to remove any visible debris. Careful attention should be focused on the lumens and working channels of all endoscopes. Lumens and working channels should be irrigated with a large syringe or a manufacturer-specific irrigating device. This is done first with detergent or enzymatic solution to help remove any residue, followed by a water rinse until it appears clear. Using the appropriate-size flexible brush will allow for proper cleaning of the lumens and working channels. Once the brush exits the tip of the scope, the bristles should be cleaned before pulling the brush back into the internal channel [6]. Brushes are available in a variety of sizes and shapes to accommodate any manufacturer's endoscopes, and proper selection is essential for prevention of damage to the endoscope (Figure 1.3). Use of newly prepared cleaning

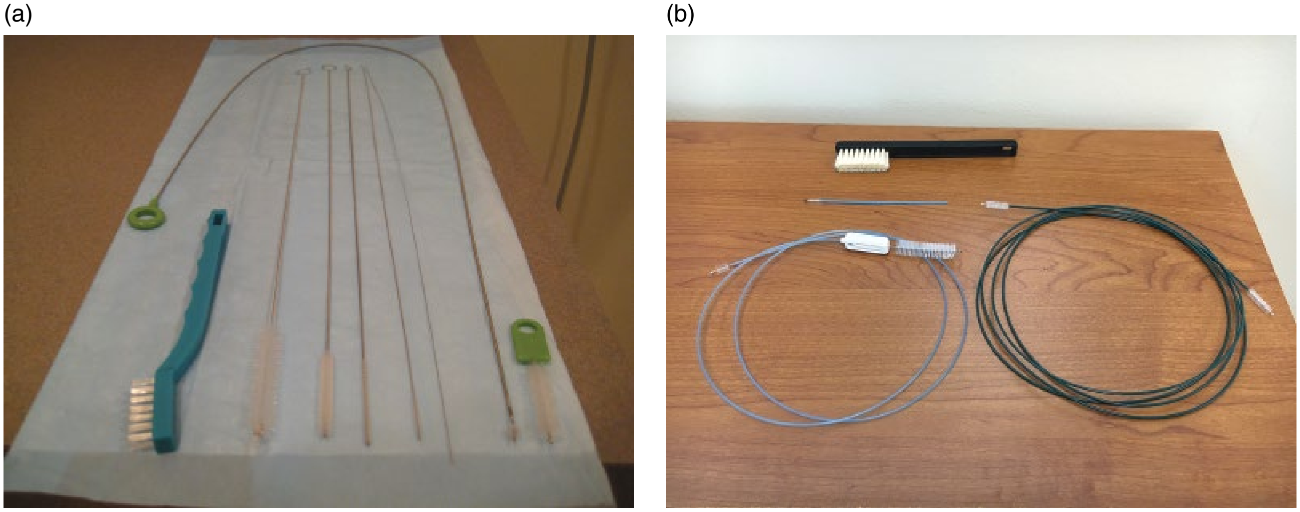

**Figure 1.3** (a) Examples of various cleaning brushes. (b) Examples of brushes and their tips.

solution prior to cleaning of each endoscope is most effective and helps prevent cross-contamination [13, 14].

A washer/sterilizer is designed to have several cycles, starting with a cold water pre-rinse, followed by a high-temperature wash cycle with an alkaline low-sudsing detergent, a neutralizing cycle, and then by a final rinse, steam sterilization, and a drying cycle [9, 11]. An ultrasonic cleaner functions by cavitation. Ultrasonic energy is passed through a water bath, creating microscopic bubbles that implode. The implosion process creates a suction action that pulls soil and foreign body matter away from instrument surfaces [9, 11]. Instruments that contain plastic or rubber should not be placed in an ultrasonic cleaner. The washer/decontaminator is a single or multi-chamber unit that cleans using an alkaline low-sudsing detergent with a spray force action and heat during the drying cycle. Multi-chamber units allow multiple single tasks to be performed simultaneously including a cool-water rinse, pre-wash with an enzymatic cleaner, wash cycle with detergent, ultrasonic cleaning, pure hot water rinse, and high-temperature drying [9, 11].

## Protection, handling, and maintenance of instruments

Protection, proper handling, and maintenance of instruments are vital in maintaining the efficacy of instruments as well as keeping instrument replacement costs down [17]. During and immediately following a procedure, heavily soiled instruments should be immersed in warm water to prevent the onset of corrosion, pitting, and rusting [11, 17]. Precleaning helps to remove debris or bioburden and prevent it from drying on the instrument. If not removed completely debris could cause an obstacle in the next steps of reprocessing and be a potential source of cross-contamination. When using flexible or rigid endoscopes, the working channel should be flushed immediately after use to prevent bioburden from drying inside and the external part should be wiped down to remove visible debris [6].

Proper handling of instruments is a crucial part of maintaining an instrument's function, especially when setting up a procedure and during reprocessing. This step is often overlooked in a careless manner due to one's haste in preparing for the next procedure. Any delicate instruments such as telescopes, flexible scopes, light cables, and fine instruments such as microinstruments must be handled in a specific manner. During a procedure these instruments should be kept in a separate location on the sterile field/setup to avoid other instruments from being placed on top of them and causing potential damage. When transporting delicate instruments to the soiled processing room they should be placed in a specific labeled biohazard container designed for instrument transport [12]. Flexible scopes and light cables must not be over-coiled while on the sterile field/setup or during transport; this will help prevent the internal fiber optics from becoming cracked or broken.

After cleaning, instruments should be checked for their function and lubricated when recommended by the manufacturer with a water-soluble lubricant [4]. Lubrication also helps prevent rusting and maintains the function of any movable piece, such as a Leur Lock part.

## Methods of sterilization

Sterilization can be achieved by way of several approved methods. These methods include using steam, ETO gas, peracetic acid, or hydrogen peroxide gas plasma.

Each method has its advantages and disadvantages along with specific indications for use. The manufacturer's guidelines and IFU for any instrument must be followed when selecting which method to use to ensure instrument viability and appropriate sterilization [18]. The healthcare setting will determine which method is suitable for the facility's operational workflow. Monitoring and documentation of the effectiveness of any sterilization method is a mandatory requirement and must be followed according to your facility's policy and procedure guidelines.

### Steam sterilization

The process of steam sterilization occurs in a steam autoclave unit designed to produce boiling water at 121 and 132 °C. A pressure of 103.42 kPa further produces steam to penetrate packaged or wrapped instruments or instruments in sterilization containers to kill any microorganisms present, including spores [19]. In order for steam sterilization to be successful the following standards are required: direct exposure to pressurized steam, a specific temperature, and a specific length of time [4].

There are types of cycle in a steam autoclave. One is the gravity-displacement cycle which removes air by the force of gravity from the top downward. Another method is the prevacuum cycle, in which the air is removed via a vacuum pump; this is also referred to as dynamic air removal [4]. The temperature and exposure time vary depending on the type of autoclave unit and the contents of the load.

A common cycle consists of 15 minutes of preheat, 15 minutes of pressurized steam, and 5–15 minutes of cooling [19]. Steam sterilization has been in existence for a long time and it is recognized to be one of the most effective, safe, and economical sterilization techniques [20].

One major disadvantage of steam sterilization is the inability to sterilize heat-sensitive materials, such as plastic or some rubber materials. Some advantages are that it is a short process, allowing a quick turnaround of packaged items, and it can be used in any healthcare setting due to the availability of various sizes of autoclave, including a table-top version which can be used in an office setting. However, some healthcare systems are moving away from table-top steam autoclaves due to the age of the technology, and the lack of quality control and biological indicator monitoring. Hence, critical items that need to be sterilized are transported to a hospital facility or a designated outsourced instrument processing facility with free-standing steam autoclaves. Depending on the cost, outpatient office settings can purchase various disposable, one-time-use, single instruments or use reusable instruments.

### ETO

ETO has the ability to sterilize heat- and moisture-sensitive instruments and medical devices, such as ones made of plastic or rubber, flexible scopes, and other instruments with lenses. ETO sterilization is a lengthy process, lasting 12 hours or more, which decreases the availability of a center's instruments. The process must be carried out in an area with proper ventilation, vent-failure alarms, and a special sterilization chamber. Careful monitoring of ETO concentration must be maintained in work areas to prevent potential injury to healthcare personnel. Due to ETO's high flammability it is mixed with inert gases, such as carbon dioxide or a fluorinated hydrocarbon, to decrease the risk of fire. In recent years hydrocarbons such as Freon 12, which used to be mixed with ETO for sterilization, have been found to contribute to destruction of the Earth's ozone layer. Therefore, since 1998 there has been a significant decrease in the use of ETO for sterilization, since other methods have been introduced [20]. Other disadvantages of ETO are it has the potential to cause harm to healthcare personnel if there is exposure, either acute or chronic. Irritation to the eyes or skin may occur from acute exposure. Chronic exposure may lead to hematologic changes, increased risk of spontaneous abortion, and some forms of cancer [4].

### Peracetic acid

In 1988 a low-temperature sterilization method using a peracetic acid compound was introduced for medical and surgical instruments, including endoscopes and instruments with lumens. Peracetic acid is an oxidizing agent composed of acetic acid, hydrogen peroxide, and water but has the disadvantage of being corrosive [21]. To allow for sterilization with peracetic acid, the STERIS Corporation in Mentor, Ohio, USA manufactured a sterilant of 35% peracetic acid and a noncorrosive chemical. This sterilant was packaged in a sealed, single-dose container and was designed to be used in the manufacturer's table-top sterilizer. This system was for "just in time" use, and so it did not require instruments to be wrapped or packaged. The table-top system was equipped with covered tray inserts to accommodate various sizes of flexible endoscopes, rigid endoscopes, and other instruments. To circulate the sterilant and rinse water through the lumens and working channels of endoscopes, specific connecting tubes were designed to attach to the different styles of scopes.

This sterilization process required filtered water of 50 °C to dilute the sterilant to a 2% concentration and the system was designed to empty the liquid concentrated sterilant via a drainage system that had to be connected to the facility's waste management line. The final phase removed excess water by passing clean filtered air through the machine's chamber, including the tubing connected to the lumens and working channels of the scopes. This table-top unit was equipped with a computer controlling the cycle's temperature, duration, and verification of completion status. Another feature of this unit was it allowed a diagnostic cycle to be run before daily use to ensure the unit had full functionality. An internal sensor would stop the unit and abort the procedure if an error in the process was detected [4, 21].

In December 2009 the US Food and Drug Administration (FDA) ceased to allow the use of the original STERIS I system due to it being unable to sterilize instruments as originally intended. The system may not have performed appropriately and therefore caused possible transmission of microorganisms to patients and healthcare workers and improper instrument function [22].

But in April 2010 the FDA approved a newly designed liquid chemical sterilization system known as the Steris System 1E Liquid Chemical Sterilant (SS1E), which uses a peracetic acid-based germicide to sterilize medical instruments such as flexible endoscopes. The system uses filtered tap water that is exposed to ultraviolet rays to eliminate microorganisms such as fungi, protozoa, and bacteria in the water. Once the process is completed the instrument or device is ready for use or can be placed in storage if not needed. Since this system uses filtered tap water, which is not sterile, critical items are contraindicated for this method [22–24].

## Gas plasma

The newest method of sterilization is hydrogen peroxide gas plasma sterilization, which has been available in the United States since 1993. This low-temperature system allows for sterilization of instruments, especially heat-sensitive or delicate ones, in just 60–75 minutes, depending on the model [20].

This technology is based on gas plasma, which has been referred to as the fourth state of matter (i.e. liquids, solids, gases, and gas plasmas) [4]. There are five phases of this process: the vacuum phase, injection phase, diffusion phase, plasma phase, and vent phase. Terminal sterilization occurs after these five phases have been completed.

The positive aspects of this system are there are no toxic fumes, no plumbing, no aeration time, and no ventilation system required. The compact, free-standing system requires a small area and an electrical source [21].

## Immediate-use sterilization

Flash sterilization, or immediate-use steam sterilization (IUSS) [10], is a high-temperature, high-moisture process used to sterilize wrapped or unwrapped instruments rapidly for just-in-time use. This method is most useful in an emergency situation when an instrument becomes contaminated during a procedure and there is no sterile replacement. Other reasons for using this method may include a low-volume inventory of specialty instruments that are needed for back-to-back procedures, or that a surgeon brings a specialty instrument required for a procedure that is not available in the healthcare facility. However, these reasons should be resolved by purchasing the appropriate amount of instruments based on the volume of cases and improved communication with surgeons in advance if any specialty instruments are needed for the case. These instruments can be brought to the healthcare facility and processed according to the manufacturer's guidelines in a timely manner with the proper communication and planning.

During the last 10 years, immediate-use sterilization in healthcare facilities has come under close scrutiny due to an increase in surgical site infections (SSI) in patients who had an immediate-use-sterilized item used or implanted during their procedure [4]. Although it is an approved method of sterilization for immediate use, excluding heat-and moisture-sensitive items such as flexible endoscopes or implants, it has become a controversial method.

IUSS is not effective if the instrument or device has not been appropriately cleaned, decontaminated, and rinsed according to the manufacturer's instructions. The cleaned item to be sterilized is placed in an open mesh pan or a specially designed rigid container with a lid that allows for rapid penetration of steam [4]. Once the sterilization cycle has been completed the covered, sterile item is transported to the point of use. Ineffective cleaning and sterilization can result in a SSI, increased length of hospital stay, increased hospital costs, and liability. As of 2014, the Joint Commission has included in their National Patient Safety Goals a focus on prevention of SSIs, which can be caused by instruments being improperly cleaned and processed by IUSS [25].

Multiple issues need to be considered when approving this method of sterilization in your healthcare facility. A most crucial issue is the location where the instrument will be cleaned prior to sterilization. It is ideal for the instrument to be processed in a designated soiled utility room with negative pressure and 10 air exchanges per hour [26]. If there is no designated soiled utility room within the operating environment then the instrument should be brought to the central sterile processing department for adequate processing. Location of the immediate-use sterilizer will determine whether pan or container method should be utilized, such as an open pan or a steam-penetratable container with a lid. With the implementation of IUSS, healthcare facilities are placing intended sterilizers for immediate use in close proximity to specific operating or procedure rooms to assist in aseptic transport to the sterile field. Healthcare personnel retrieving containers from the sterilizer and transporting sterilized devices must don heat-sensitive gloves to avoid the potential risk of burning. Once the item is accepted into the sterile field it must be cool before use to prevent a patient burn injury. If necessary the immediate-use-sterilized item should be placed in sterile saline to cool before use.

Depending on the type of sterilizer and the composition of the item to be sterilized for immediate use there are specific guidelines from the American National Standards Institute/Association for the Advancement of Medical Instrumentation (ANSI/AAMI) [24]. The temperature regardless of the sterilizer should always be 132–135 °C. The recommended sterilization exposure time ranges from 3 to 10 minutes and depends on the type of sterilizer and the contents of the load. Drying times of 0–1 minute are recommended for gravity-displaced sterilizers and will also depend on the item and the sterilizer manufacturers' instructions [4, 27].

Quality monitoring of the sterilizer's daily function and each cycle along with documentation is a vital part of the sterilization process. The types of monitoring for include physical, efficacy, chemical, and biological rapid readouts. Any breakdown in the process, such as an incorrect temperature or a positive biological indicator, must be reported immediately to management and the physician for further follow-up and corrective action.

Education of staff and documentation of competence of the procedure for immediate-use sterilization are other important requirements. Initial and annual training should be provided to all involved healthcare personnel, along with return demonstration by the staff to validate their competency in immediate-use sterilization [27, 28].

To avoid overuse of immediate-use sterilization, it is recommended to increase the inventory of high-volume items that are being sterilized for immediate use, to review the schedule the day before to anticipate instrumentation needs, to expedite immediate sterilization after use of surgeon or procedural specialty items to allow for availability of sterile equipment, and to take receipt of implants in a timely manner to allow for a full sterilization process to take place prior to the procedure's start time [28, 29].

## Other alternatives

HLD is the other alternative to sterilization in specific healthcare environments. HLD can be expected to kill all microorganisms, with the exception of a few bacterial spores when a high number is present [4, 6, 19]. The steps of this process are similar to sterilization but do not include packaging or placement of an item in a sterilization container. The steps of this process are precleaning, cleaning, rinsing, drying, immersion in disinfectant solution, sterile-water rinsing, drying, and immediate use or storage. As of March 2015, the FDA approved various agents for HLD: ≥2.4% glutaraldehyde, stabilized hydrogen peroxide, peracetic acid, and ≥0.575% *ortho*-phthalaldehyde (OPA) [5, 30]. Some of these agents may be mixed together at certain strengths to make one disinfectant solution. The required soak time and temperature of the solution differs based on the disinfectant used. Aldehyde agents are most commonly used for HLD, especially for the manual process. Glutaraldehyde, which is the most commonly used solution, has an alkaline pH and can be used for 2–4 weeks or 30 days depending on the formula, but must be checked daily for potency [19, 30]. The disinfectant solution to be used for the instrument or medical device must be approved by the instrument or device manufacturer and be stated in the IFU guidelines. Prior to use, healthcare personnel must don a new set of PPE, including a full face shield, impervious gown with sleeves, and nitrile gloves. The chemical disinfectant must be prepared in a well-ventilated area with a low traffic pattern.

Depending on the IFU, some flexible endoscopes can be processed in an automatic endoscope reprocessor. This is a closed system that allows the scope's external surface to be fully exposed to the disinfectant solution. Connection tubing is attached to the lumens, allowing internal channels to be purged with the solution as well. The benefit of this closed system is it lessens the chance for exposure to the chemical disinfectant solution [6].

With a shift of hospital procedures to outpatient healthcare facilities, there is an ever-present concern about HLD and sterilization of semicritical and critical instruments and medical devices. Nationwide in the United States there is an awareness of neglect in the required guidelines for processing of semicritical items by HLD, especially all flexible endoscopes, including cystoscopes. Healthcare-associated infections are on the rise and connected to contaminated endoscopes due to improper reprocessing [10, 31]. In September 2015 major regulatory organizations of the Department of Health and Human Services – the Centers for Disease Control (CDC) and the FDA – communicated an alert to healthcare staff regarding the importance of properly processing (cleaning, disinfecting, decontamination, and sterilization) semicritical and critical medical instruments and devices. The FDA recommended that any instrument or medical device that passes through an endoscope and comes into contact with sterile tissue, such as a biopsy forceps, must be sterilized prior to use [7, 31].

There are two factors that must be in place to ensure the proper process for cleaning and disinfecting instruments or medical devices prior to HLD or sterilization. One is the physical area or layout and the second is training and education of the staff preparing instruments for HDL or sterilization. The physical layout should consist of two separate work areas regardless of the healthcare setting, allowing a dirty-to-clean flow from one room to the other. An instrument processing room (dirty) receives the soiled instruments for cleaning and decontamination. A HLD system can be found in this room as well. The purpose of the adjacent room (clean) is for instrument preparation, sterilization, and storage of disinfected flexible scopes when necessary. Instruments stored in this room must be either sterile or HLD, and ready for use. Ideally, a third room for instrument storage would be beneficial to allow the clean room to be utilized just for instrument processing and sterilization. In some outpatient healthcare facilities there can be a substerile room adjacent to the procedure room that accommodates a free-standing steam sterilizer. This is for any instruments that can be sterilized as per the manufacturer's IFU, such as flexible instruments, vasectomy trays, or rigid cystoscopes. In the instrument processing room there should a designated dirty sink, a clean sink, and a hand-washing sink. A double sink should be designated as either dirty or clean and therefore there must be yet another two sinks, one for dirty or clean and the other for hand washing. The latter should have an eyewash station attached, in case there is exposure of the eyes to bodily fluids or any chemicals used in this area.

Designating a clean and dirty sink is to help prevent the possibility of cross-contamination while cleaning the instruments or medical devices. Due to certain circumstances some outpatient healthcare facilities may only be able to have a double sink, with one used for cleaning and the other for rinsing. These sinks must be wiped down in between uses with a bleach-based Environmental Protection Agency (EPA)-registered hospital-grade surface disinfectant after cleaning dirty instruments and before rinsing. The sinks should be equipped with a gooseneck-style faucet with winged handle controls to allow for proper water temperature adjustment. Sensor-controlled faucets are not recommended as it is difficult to obtain a precise water temperature that is adequate for cleaning and decontamination of instruments or medical devices [32].

Before placement in the disinfectant solution all items must be rinsed thoroughly to remove any residual detergent and dried completely to prevent dilution of the disinfectant solution once an instrument is immersed [9]. Once an instrument is fully immersed, if it has lumens or working channels the disinfectant solution must be flushed through with a syringe three times for internal exposure. The syringe must remain in place for the full indicated soak time [32, 16]. Exposure time ranges from 10 to 45 minutes with a solution temperature of 20–25 °C [5]. After the recommended exposure time, the instrument is transferred to an adjacent basin filled with sterile water. The instrument is fully immersed in sterile water and the external surfaces are wiped with a lint-free cloth. If the instrument has lumens or working channels the sterile water must be flushed through three times to remove any residual disinfectant solution. The final step before use or storage is to thoroughly dry the instrument and, if it has lumens or working channels, air is to be forced through with a large sterile syringe. For use in a procedure the instrument should be transferred to a sterile sheet or drape, covered in a sterile manner and transported to the point of use. If a scope is to be placed in storage it is recommended that it be hung in a well-ventilated drying cabinet that supplies forced air in cycles. Scopes are hung in a vertical position and connected to plastic tubing which enables the transport of forced air. This drying process prevents recontamination from residual fluid that may stay dormant in the scope and harbor bacterial growth, further promoting thorough drying of the internal channels of the endoscope [5]. The drying process can be enhanced with filtered, low-pressure medical air, a large syringe filled with air, or by flushing with 70% alcohol according to the manufacturer's guidelines or IFU. If the scope has detachable pieces they are to be removed prior to storage to stop residual moisture from flowing into the inner channel and aiding in growth of microorganisms [6, 7, 10, 12, 32, 33]. Monitoring of the room's temperature and humidity with a traceable digital meter is recommended by the CDC when storing flexible endoscopes [12].

According to the Association of Operating Room Nurses (AORN), the safest practice in the disinfection of endoscopes is to disinfect at the end of each day's use, again before the first use of the next day, and again before each use throughout the day [34].

Any healthcare facility that utilizes chemical disinfection must provide a safe environment for the setup and for the protection of their healthcare personnel. The solution, once activated and dispensed, must be kept in a covered container with a tight-fitting lid in a well-ventilated area. A free-standing or vented chemical fume hood is recommended for aldehyde solutions. With a free-standing fume hood, a carbon filter should be installed and must be changed and disposed of according to the manufacturers' instructions [9]. Fume hoods are available in various sizes and designs to accommodate your needs (Figures 1.4 and 1.5). A spill kit must be readily available in the event of a spillage of the chemical solution. Disposal of the chemical solution once deemed ineffective or on expiration must follow state and local

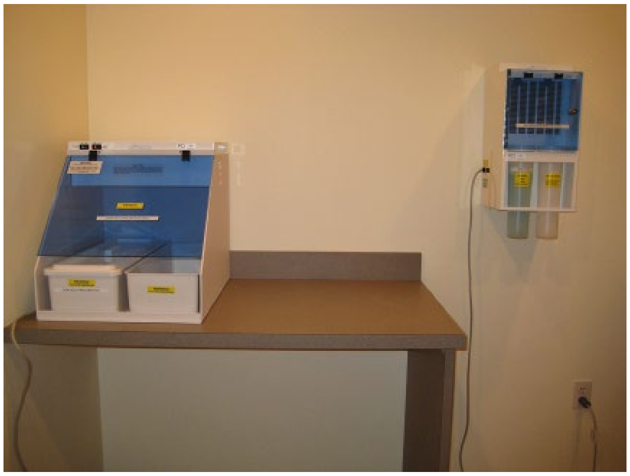

**Figure 1.4** Table-top and wall-mounted fume hoods for aldehyde solutions.

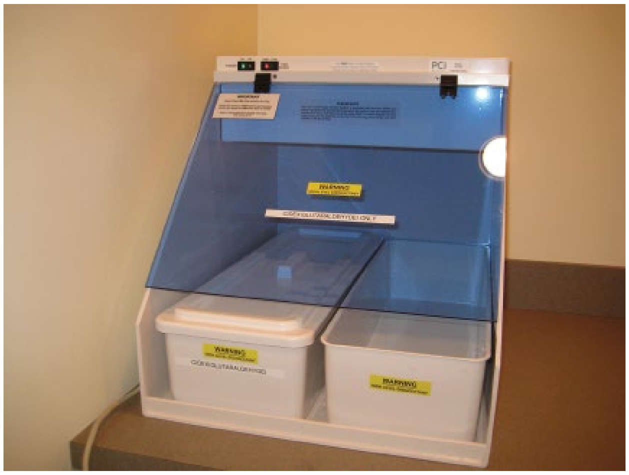

**Figure 1.5** Table-top fume hood for aldehyde solutions.

regulations. A neutralizing agent should be added to the solution to deactivate its potency. This can take from 5 to 15 minutes before disposal of the neutralized solution can occur [6].

In 2014, The American Urological Association (AUA) and the Society of Urologic Nurses and Associates (SUNA) published a joint white paper on the reprocessing of flexible cystoscopes. This is an excellent resource for any healthcare facility that utilizes flexible cystoscopes and it includes an "In-Office Disinfection of Flexible Cystoscopes Quick Reference Tool" which can help guide the instrument processing team [6].

OPA is a newer high-level disinfectant that was approved by the FDA in 1999. It is less potent than glutaraldehyde, is not an irritant to the eyes and nasal passages, and has a soak time of just 12 minutes. Prior to 2004 this chemical was ideal for the HLD of flexible cystoscopes, but due to reports of patients with bladder cancer experiencing an anaphylaxis-like reaction after cystoscopy utilizing scopes processed with OPA, this chemical disinfectant is currently contraindicated for cystoscopes and any urological instruments that will have contact with the bladder, according to the CDC and the manufacturer [6]. OPA is the disinfectant of choice for an ultrasound rectal probe, a semicritical device, which is used for guidance during a prostate needle biopsy procedure or for prostate measurement. Prior to the immersion and soak time, an ultrasound probe must be cleaned, wiped, rinsed, and dried according to the manufacturer's guidelines. A newer, alternative method of HLD for intracavity ultrasound probes is a 35% hydrogen peroxide mist system that is now available and approved by the FDA. This system not only disinfects the part of the probe (the head) that has contact with mucous membranes but it also disinfects the part of the probe used by the physician's hand to position the probe (the handle) and which therefore has the potential for contamination due to its function [33, 35, 36].

Documentation of the HLD process includes several factors. The initial setup of the HLD solution must be tested for its efficacy and level of concentration, known as minimal effective concentration (MEC). If the MEC fails the check before the intended expiration date the solution must be discarded [6]. The solution is tested every day with a reagent strip made by the solution's manufacturer, and the solution is also tested before use. The result is documented in a log book. When an item is intended for use the following information must be documented in the log: date, test strip result for effective solution concentration (positive or negative), temperature of the solution, name of the semicritical item, serial number if applicable, time it was placed in the solution, time it was removed, patient medical record number, cleaning method (manual or automated), soak station number if there is more than one on site, and name of person performing the HLD [6].

Each healthcare facility will determine which method of sterilization is best for their practice. In a hospital setting, steam, gas plasma, and peracetic acid are preferred. Some ambulatory healthcare facilities have a steam autoclave, and also use gas plasma and/or peracetic acid for sterilization methods. As for HLD semicritical items, aldehydes are used primarily to carry out this process.

Several organizations have developed guidelines for sterilization and disinfection of instruments and medical devices. The AAMI developed recommended practices for steam sterilization in healthcare facilities. The CDC put together guidelines for disinfection and sterilization in healthcare facilities and guidelines to prevent surgical infections. The AORN have recommended practices for cleaning and caring for surgical instruments, sterilization, the use and care of endoscopes and HLD in the perioperative setting. The Joint Commission has standards (IC.02.02.01) to reduce the risk of infection associated with medical equipment, devices, and supplies; this includes cleaning, disinfection, sterilization, and storage [37]. In 2013, this standard was identified as one of the top five least-adhered-to requirements for all healthcare facilities. It fell into the category of an immediate threat to life due to a break in technique of sterilization and HLD of instruments and medical devices [29]. When surveying a healthcare facility the surveyors are looking for documentation of staff orientation, training, and competency of the relevant processes. Other requirements that they will focus on are quality monitoring and adherence to the manufacturers' IFU when processing medical devices or instruments. These organizations' recommendations serve as a resource for your policy and procedure manuals and a guide to provide best practice in your healthcare facility.

Education and the training of staff is a current focus in healthcare facilities that carry out HLD and sterilization processes. In the hospital setting the staff in the central sterile department maintain certification for instrument technicians after staff have received the required training and acquired their certification. Those who work in nonhospital settings and who are not certified should receive appropriate hands-on training and education sessions to ensure they understand all aspects of the cleaning, decontamination, disinfection, and sterilization processes, including the safe use of all equipment involved. All trained staff should have a documented initial and annual competency kept in their employee departmental file for each process and piece of equipment used [15].

## Conclusion

The ultimate goals of instrument sterilization and HLD are to maintain a safe patient environment, provide quality patient care, and positive surgical or procedural outcomes with no evidence of infections. It is the responsibility of the healthcare facility to develop policy and procedures and evidence-based guidelines for the reprocessing of all critical and semicritical patient care items. These policies and guidelines should identify whether disinfection or sterilization is indicated as per the manufacturer's guidelines and the Spaulding classification system. The healthcare personnel responsible for the full cycle of reprocessing of these items should be trained and certified to perform all aspects of this task. In the physician office setting there should be designated personnel who have been trained and deemed competent to carry out the tasks of reprocessing patient care items based on the availability of soiled and clean work areas. Continuing education should occur to keep the trained and certified personnel informed of any changes in process or equipment use, and as an annual scheduled event.

## Introduction

According to a 2009 National Council on Radiation Protection and Measurements (NCRP) report, the total ionizing radiation exposure to United States citizens had almost doubled over the previous two decades [1]. The report attributed this to increased exposure from computed tomography (CT) scans, image-guided fluoroscopic procedures, and nuclear medicine studies, which were estimated at 67 million, 17 million, and 18 million, respectively. During 2006, these imaging modalities constituted 89% of the total annual radiation exposure [1, 2]. On the other hand, recent studies have shown significant worldwide increase in the prevalence of stone disease [3, 4]. In the United States, prevalence increased from 5.2% in 1994 to 8.8% in 2010 [5]. Similarly, in the United Kingdom, renal colic episodes increased by 63% from 2000 to 2010 [5]. This was associated with marked decline by 83% in open surgeries and a marked increase in minimally invasive endourologic procedures such as shockwave lithotripsy (SWL), which increased by 55%, and ureteroscopy, which increased by 127% [5]. The increase in the incidence of stone disease and management with endourologic procedures is not without risks. Since ionizing radiation is not only an integral part of modern endourologic interventions but also constitutes the basis for diagnosis, preoperative planning, and post-operative follow-up, it is important for the urologists to have an intimate knowledge of radiation safety measures and to minimize ionizing radiation as much as possible to themselves, operating room personnel, and most importantly to their patients. This chapter discusses the state of the art in radiation safety measures during diagnosis, treatment, and follow-up. To follow radiation safety measures, one needs to understand how ionizing radiation is generated in the first place. Therefore, this chapter will start by explaining the anatomy of the X-ray tube and the generation of X-rays. It will then go through potential hazards of ionizing radiation. At the end of this chapter, readers will have developed strategies in lowering radiation exposure during diagnosis, treatment, and follow-up of their patients requiring endourologic procedures.

## Basic terminology and International System of Units in radiology

According to the International System of Units (SI), the absorbed dose, measured in Grays (Gy) or joules/kg, is the amount of energy absorbed per mass of tissue [6, 7]. To measure the biological effect of radiation on human tissue, the mean absorbed dose in an organ or tissue is multiplied by radiation weighting factor to calculate the "equivalent dose." The radiation weighting factor differs according to the type of radiation. For X-ray imaging (photons), it equals 1. Therefore, the mean absorbed dose and the equivalent dose are numerically equal. The SI unit for equivalent dose is the Sievert (Sv). Thus, 1 Gy equals 1 Sv. As the doses used for radiographic imaging are generally very low, milliSieverts (mSv) is used as a standard nomenclature describing doses administered [8]. The probability and severity of harmful effects from the same value of equivalent dose of radiation differ among different body organs and tissues.

The International Commission on Radiological Protection (ICRP) refers to the combination of probability and severity of harm as "detriment." In order to determine the combined detriment from stochastic effects due to the equivalent doses in all body organs and tissues, the "effective dose" is described. It is calculated by multiplying the equivalent doses in each organ by a tissue weighting factor ($W_T$), and the results are summed

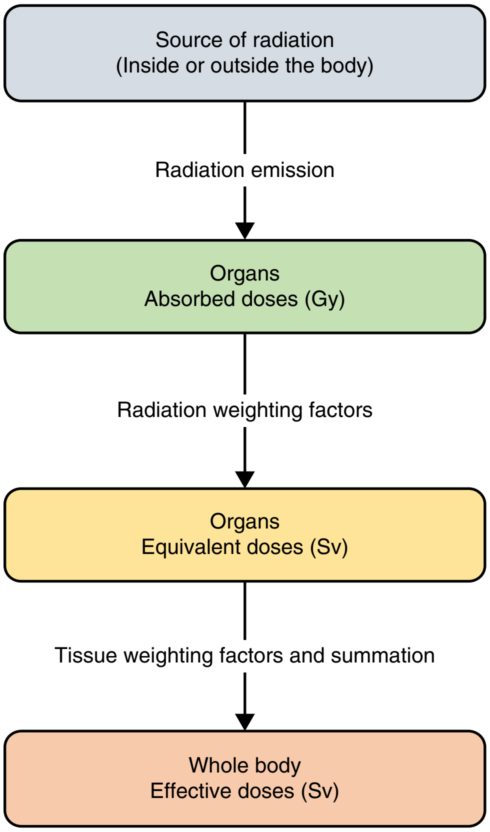

**Figure 2.1** The relationship between absorbed dose, equivalent dose, and effective dose. Reproduced with permission of Sage Publications Ltd.

over the whole body [8] (Figure 2.1). The SI unit for effective dose is also the Sievert (Sv). The weighting factors vary according the radiosensitivity of each organ and are determined by the ICRP. For example, a $W_T$ of 0.12 was described for red bone marrow, colon, lung, stomach, breast, kidney, pancreas, and prostate, a $W_T$ of 0.08 for gonads, and $W_T$ of 0.04 for the skin and brain [8].

Another factor used for estimation of radiation exposure is the dose area product (DAP), which is calculated from the radiation dose to air multiplied by the area of the X-ray field. It is expressed in $Gy/cm^2$ and it could be reliably used to estimate the effective dose by combining the DAP with the appropriate coefficient (which varies for the irradiated portion of body and the protocol used) derived from Monte Carlo simulations with anthropomorphic digital phantoms [9–11]. The size-specific dose estimate is considered as a novel method of reporting a patient's radiation dose. It is calculated by multiplying CT dose index volume (CTDIvol) by a size-dependent conversion factor. It accounts for patient size in a way that the increase in patient size decreases the size of specific dose estimates [12, 13]. The average medical imaging exposure ranges from 0.7 mSv for a single plain kidney-ureter-bladder (KUB) film to 18 mSv for a CT scan, depending upon device settings and body habitus. Even with relatively low radiation doses, the concern over excessive radiation exposure has grown recently due to the exponential rate at which medical imaging is used [14].

## How are X-rays generated?

Prior to understanding the hazards of radiation and methods of protection, it is wise to briefly consider the principles of radiation production. The basic components required for X-ray generation are (i) rotating anode (usually made of tungsten which is capable of handling a high heat load without warping or vaporizing), (ii) cathode (source of electrons), (iii) high voltage source, (iv) X-ray vacuum glass tube, (v) housing (steel casing which provides shielding to prevent leakage of stray X-rays), and (vi) collimator (which specifies the X-ray field).

Within the shielded housing, X-rays are generated when a high voltage is applied between the cathode and the rotating anode. The amount of electrons liberated from the cathode is directly proportional to the amount of current applied in milliamps (mAs). A large voltage potential (kVp) in the range of 50–120 kVp is usually required. Higher energy X-rays will penetrate deeper into tissues and penetrability of X-ray photons is directly proportional to the average energy of the photons generated. Hence, obese patients are expected to receive higher doses of radiation to obtain appropriate image quality compared with thinner ones. Therefore, the potential energy is adjusted to compensate for differences in patient body mass index (BMI). X-rays exit the housing through a narrow beryllium window, which permits the passage of only focused X-rays. Lead collimators further restrict the area of exposure, limiting the radiation area and, in turn, the amount of scattered radiation from the patient to operating room personnel (Figure 2.2) [6, 7].

The amount of X-ray photons, or radiation, generated by individual electrons varies depending on the proximity to the target material's nucleus. Therefore, a direct impact transfers a large quantity of kinetic energy and generates maximum energy X-ray photons, while a more distant interaction generates weaker X-ray photons. The X-ray photons produced is termed *bremsstrahlung*, which translates to "braking radiation." The variability of distance from the nucleus therefore creates a spectrum of energy emitted from the X-ray tube, the *bremsstrahlung* spectrum. The mean energy of the photons across the spectrum is typically equal to one-third the total potential difference generated by the voltage.

The energy of photons is an important consideration because the higher the energy of the photon, the more

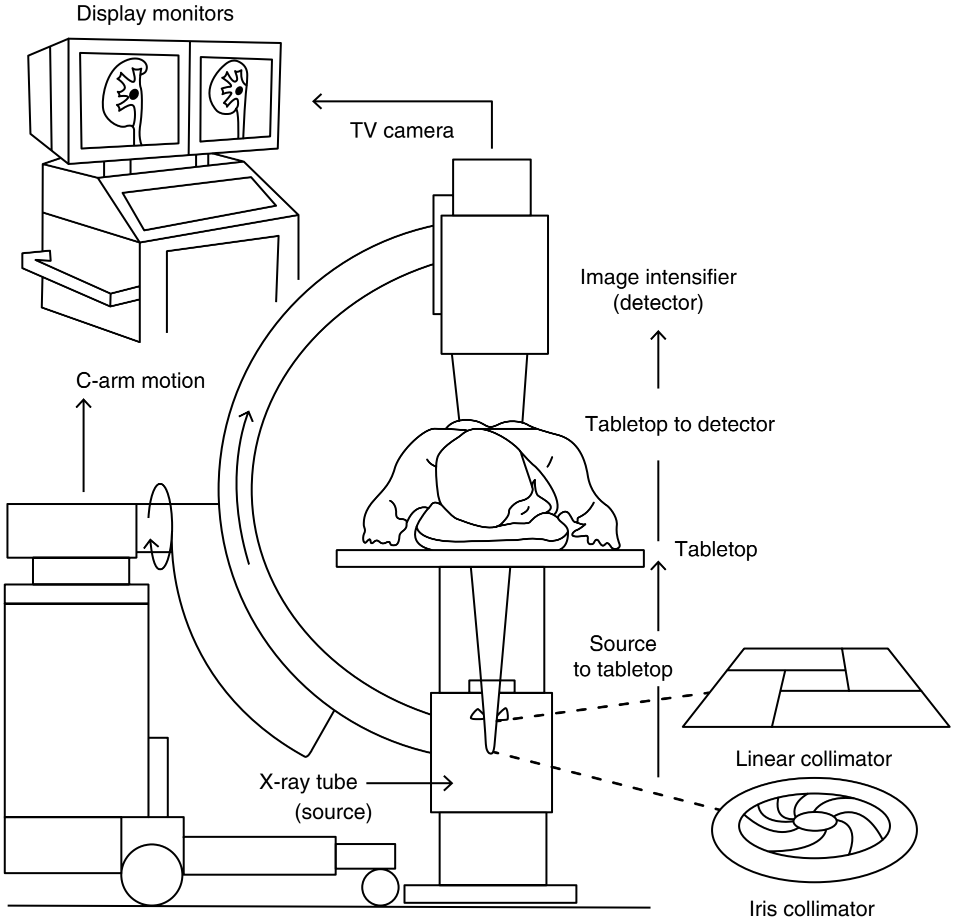

**Figure 2.2** X-ray generator set-up. Adapted from Wheeler AH. Therapeutic injections for pain management. http://emedicine.medscape.com/article/1143675-overview#a3 (accessed 15 July 2016).

shielding is required and the more readily the photon will penetrate tissue. Shielding for the X-ray housing is restricted to less than 100 mrad/hour at 1 m to prevent excessive leakage rates while the tube is operating at maximum potential difference and current. Photons leave the tube through a small opening in the shielding and are directed towards the area of interest (Figure 2.2). Filters are then generally applied to these diagnostic X-ray beams. These filters attenuate the lower-energy photons which do not have sufficient energy to reach the detector and therefore are not of clinical benefit. The electrons with energy high enough to penetrate through the filters are focused by the collimators through the tissue area of interest. Typically, the collimators further restrict exposure to the patient and the operator by eliminating radiation exposure outside the area of interest (Figure 2.2).

The quality of the image obtained is significantly reliant on the energy level and quantity of the electrons reaching the detector. X-ray photons need to be of high energy enough to penetrate through the tissue but low energy enough to limit "over-exposure" of the detector. Therefore, the most controllable aspects of diagnostic imaging equipment are (i) the potential difference (kVp), which determines the amount of energy in X-ray photons, (ii) the current (milliamps), which determines the number of electrons that create photons for a given time period, and (iii) exposure time, which combines with the current to determine the total quantity of X-rays produced. Because radiation exposure is proportional to the square of kVp and linearly related to milliamps, ideally it is better to increase kVp prior to increasing milliamps to enhance image quality. Conversely, if an initial image is "over-exposed," reducing current will greatly reduce radiation dose.

Emitted X-rays have three potential fates as they interact with living tissue: (i) some X-rays are absorbed by dense tissues such as bones, (ii) others penetrate soft tissues to reach the image intensifier, and (iii) 0.1% of X-rays are scattered 90° to the incident radiation, exposing bystanders. By placing the image intensifier above the patient and the source below the patient, the amount of scattered radiation exposure to the surgeon can be minimized. Furthermore, leakage from the tube itself is shielded and is further away from the operating surgeon's head and body (Figure 2.2).

Understanding the basic principles and mechanisms of X-ray generation provides a foundation for the understanding of radiation protection. Proper equipment maintenance and inspection of shielding and filters are requisite requirements for operators of imaging equipment. Fluoroscopy units in hospitals are usually inspected and maintained annually by biomedical engineers. Nonetheless, it is important for the urologist to understand the basic electrical parameters (kVp and current) and their effects on X-ray generation leading to optimization of the image quality while minimizing dose to patients and operators. Finally, the use of collimation to limit the exposure field to precisely target the tissue area of interest can greatly restrict unnecessary exposure.

## Potential hazards of excessive radiation exposure

There are two broad categories describing the risks from radiation exposure; namely, deterministic and stochastic.

### Deterministic effects

These generally refer to a direct cell death resulting from direct exposure of a biologic tissue to high doses of radiation. This type of tissue reaction needs a threshold dose to occur; below this threshold nothing will happen and the degree of tissue response correlates with the intensity of radiation dose above the threshold. An example is the opacification of the lens of the eye or cataract formation at a threshold of 200 rad, skin erythema and depilation at a threshold of 300–600 rad, and even skin ulceration and necrosis at a threshold of 1500–2000 rad [1, 8].

### Stochastic effects

These refer to events that are likely to occur by chance irrespective of the threshold levels of radiation, and likelihood of occurrence increases with dose. However, there is no relationship between severity of the event and the dose. The stochastic risks of greatest concern are hematologic and solid organ malignancy. The proposed explanation of these carcinogenic hazards is that X-rays, as a type of ionizing radiation, possess enough energy to overcome the binding energy of the electrons orbiting atoms. Thus this energy can knock electrons out of their orbits and create ions. In biologic material, X-rays can either ionize DNA directly or produce hydroxyl (OH) radicals from the interaction with water molecules. These hydroxyl radicals in turn interact with nearby DNA and cause epigenetic responses in the form of radiation-induced genomic instability or bystander signaling, base damage, or strand breaks. While most X-ray-induced DNA damage undergoes rapid repair by different intracellular mechanisms, occasional problems in DNA repair may happen resulting in chromosomal translocations or point mutations which may lead to induction of carcinogenesis, especially in growing cells such as in infants and children [14].

Whereas a correlation between excessive radiation exposure and deterministic dermal and ocular effects exists, models used to calculate the stochastic effects associated with radiation exposure are still debated [15]. Two recent studies assessing the risks of cancer following repeated or protracted low-dose radiation exposure among 308 297 radiation-monitored workers from United States, France, and United Kingdom [16] showed that there was a linear increase in the rate of cancer with increasing radiation exposure. Workers were selected for monitoring based on conditions of being employed for at least 1 year by the Departments of Energy and Defence in the United States, the Atomic Energy Commission or the National Electricity Company in France, and nuclear industry employers included in the National Registry for Radiation Workers in the United Kingdom. After exclusion of chronic lymphocytic leukemia, there was an excess relative risk of mortality from leukemia of 2.96 per Gy with marked association between the radiation dose and mortality from chronic myeloid leukemia (excess relative risk per Gy 10.45) and doses were accumulated at very low rates (mean of 1.1 mGy/year) [16]. Another study revealed a direct estimate of the association between solid cancer mortality and protracted low-dose exposure to ionizing radiation [17]. Another international study with 407 391 nuclear industry workers from 15 countries estimated the oncologic risks following prolonged low doses of ionizing radiation exposure. The authors found significant association between the radiation dose and all cancer mortality, with excess relative risk per Sievert (ERR/Sv) of 0.97 (90% confidence interval [CI] 0.28–1.77; 5233 deaths). Furthermore, duration of employment had a large effect on the ERR/Sv and lung cancer was the only type which had a significant association among 31 malignancies studied (ERR/Sv = 1.86 [90% CI 0.49–3.63; 1457 deaths]) [18].

In another study, the risk of cancer from diagnostic X-ray in 14 developed countries was 0.6–1.8% compared with more than 3% in Japan, which has the highest estimated worldwide annual exposure [19]. Eisenberg and co-investigators studied the risk of cancer in 82 861 patients without previous history of cancer and undergoing diagnostic or therapeutic imaging following acute myocardial infarction from 1996 to 2006 [20]. The cumulative radiation exposure was found to be

5.3 mSv/patient/year. Over a median follow-up of 5 years, a total of 12 020 incident cancers were diagnosed. Every 10 mSv of low-dose ionizing radiation was associated with a 3% increase in the risk of age- and sex-adjusted cancer with a hazard ratio of 1.003 per mSv (95% CI 1.002–1.004) [20]. Additionally, Berrington de González and coworkers estimated future cancers attributable to ionizing radiation from CT scans to be 29 000 cases in the United States in 2007. Of these, 66% were females and the largest contribution (14 000) was from abdominopelvic CTs [21]. Furthermore, Smith-Bindman and co-investigators reported that 1/600 men and 1/270 women patients who underwent CT coronary angiography at the age of 40 are at risk of cancer and this risk is halved for those who were in their sixties and doubled for those who were in their twenties [22].

## Sources of ionizing radiation encountered in urology

### Diagnostic imaging

There is no doubt that most medical diagnoses are based on ionizing radiation. However, diagnostic modalities such as ultrasound and magnetic resonance imaging (MRI) are free from radiation. Plain radiography, fluoroscopy, CT, and nuclear medicine studies are associated with various doses of ionizing radiation. Traditionally, plain radiography such as KUB films was the initial imaging modality for patients with suspected nephrolithiasis with a sensitivity of 59% and specificity of 71% [23]. This low accuracy is due to the failure of plain radiographs to detect uric acid stones. Furthermore, identification of stones might be masked by the overlying bowel gases. Advantages of KUB include low cost which rendered it available worldwide and lower radiation exposure compared to other modalities (effective radiation dose of 0.2–0.7 mSv) [23, 24]. Intravenous urography (IVU) has additional advantages over KUB such as demonstration of the anatomical and functional status of the urinary system. It is associated with higher effective radiation dose ranging from 0.7 to 3.7 mSv, depending on the number of images [24, 25]. However, IVU is time-consuming and necessitates the use of intravenous contrast materials with the risk of allergic reactions and contrast-induced nephropathy

Since being invented in 1970s, CT has been largely used in medical diagnosis and intervention. During a CT scan, multiple cross-sectional two-dimensional images of a specific area are produced by a rotating source passing X-rays through the patient’s body. Later on, these two-dimensional images can be digitally combined to yield three-dimensional images [26]. In urologic practice, CT scans play a vital role in preoperative planning of percutaneous nephrolithotomy (PCNL) and SWL. For PCNL, it provides an orientation of the pyelocalyceal system and the relationship of the kidney to the surrounding organs such as the colon, liver, and spleen. In addition, preoperative non-contrast CT (NCCT) scanning forms the basis of calculating different scoring systems assessing PCNL complexity such as the S.T.O.N.E. and Seol scoring systems [27, 28]. Regarding SWL, CT is very important for calculating the skin-to-stone distance to determine whether shock waves can reach the stone. For both SWL and PCNL, it detects postprocedural complications and presence of residual stones [29, 30]. Furthermore, it is ideal for diagnosis, staging, and follow-up of most urologic malignancies [31, 32]. In addition, NCCT is the imaging modality of choice for initial evaluation of patients with suspected urolithiasis with reported diagnostic sensitivity up to 98% and specificity up to 100% [33]. It is worth mentioning that the stone protocol CT scans performed for diagnosis and follow-up of urolithiasis patients have scan acquisition parameters that differ from traditional abdominopelvic CT scans. Therefore, patients presenting with suspected stone disease to the emergency department undergo NCCT scans with acquisition parameters different from those used in the normal stone protocol CT scans to allow emergency physicians to diagnose pathologies other than stones [34, 35].

With the exception of stones encountered in patients undergoing indinavir therapy and pure matrix stones, NCCT scan can diagnose all types of urolithiasis such as calcium, uric acid, xanthine, and cystine stones [36, 37]. Furthermore, it detects other renal and abdominal pathologies which present with acute abdominal pain resembling renal colic such as diverticulitis, appendicitis, or ovarian torsion. Therefore, it is not surprising that 10–14% of NCCTs performed in the emergency departments for renal colic were associated with alternative diagnoses [38–43].

In addition to determination of stone burden, location, multiplicity, density (Hounsfield unit), and associated hydronephrosis, dual-energy CT (DECT) technology, which has been introduced in the past decade, seems to possess the potential ability for accurate determination of stone composition [44–47]. It includes dual-energy simultaneous scanning using two different energies, which permits tissue characterization. There are two currently available DECT systems: single-source DECT (ssDECT) and dual-source DECT (dsDECT). While ssDECT is assembled with one X-ray tube with rapid kV switching between high (140 kVp) and low energy (80 kVp), dsDECT is assembled with two X-ray tubes (140 and 80 kVp) and two detectors on a single gantry perpendicular to each other [48]. Several *in vitro* and *in vivo* studies have validated DECT technology for detection of stone composition using both dsDECT and ssDECT. It allows detection of stone composition based on the variation in attenuation characteristics of stones at different X-ray energies with up to 100% sensitivity and accuracy in distinguishing non-uric acid and uric acid stones, regardless of the size of stones [44, 46, 49, 50]. Furthermore, with evolving DECT algorithms, there is an application for accurate subcategorization of renal stones [49, 51]. To reduce radiation exposure, the current DECT protocol for renal stones includes the use of single-energy mode at a low dose covering the abdomen and pelvis, to recognize possible calculi in the urinary tract. Once the urinary stone is detected, a dual-energy acquisition targeted to the anatomical area of the stone is performed [37]. It should be noted that obese patients are at higher risk of more radiation exposure from CT [52]. In a recent study by Wang and coworkers, they found that obese patients are at more than threefold-increased risk of radiation exposure compared with non-obese patients during the stone-protocol CT employing automatic tube current modulation (10.22 vs. 3.04 mSv; $P < 0.0001$) [53].

Disadvantages of CT include the high cost which limits worldwide availability, and the high radiation exposure, with effective radiation doses of 4.5–18 mSv [25]. In a study by John and colleagues, patients who underwent a CT were exposed to 14.46 mSv [54]. Furthermore, the median effective radiation dose (ERD) associated with an acute stone episode and 1 year of follow-up at two American academic centers was 29.7 mSv [55]. Moreover, it was found that 20% of patients received over 50 mSv with an average of 3.5 CTs [55]. In a similar study by Fahmy et al. assessing the ERD to which urolithiasis patients are exposed during the evaluation and follow-up over the first and second year following the acute stone episode, they found that the average ERD per CT scan was 23.16 mSv (range 4.94–72.77 mSv). Furthermore, they found that 17.3% of patients exceeded 50 mSv during the first follow-up year with mean ERD of 29.29 mSv (1.7–77.27 mSv) [56]. Another study reported that a case of acute kidney stone episode that may require radiological imaging in the form of one or two KUBs, one or two abdominopelvic CT, and one IVU during the first year of follow-up may be exposed to a total effective dose between 20 and 40 mSv [24]. In addition, it has been calculated that the effective dose from CT scan of the abdomen in adult patient is roughly equivalent to effective dose from 400 chest X-rays [25].

Even some surveillance protocols using CTs have been shown to be associated with significant radiation exposure and the risk of developing cancers. Tarin and colleagues assessed the estimated cancer risks associated with the 5-year surveillance protocol of stage I non-seminomatous germ cell tumors of the testis, as recommended by the National Comprehensive Cancer Network. They reported a lifetime cancer risk of 1.5% for different age groups with lung and colon cancer accounting for most of the risk [57].

Nuclear medicine imaging procedures such as position emission tomography CT (PET CT) scans and renal scintigraphy (renal scanning) entails the use of a radioactive material, called a radiotracer or radiopharmaceutical, which is introduced into the human body by injection, swallowing, or inhalation. This radiotracer accumulates in the area of the body being examined, where it gives off a small amount of energy that can be detected by gamma camera and provides details on both the function and structure of tissues and organs being examined. These radiotracers stay within the tissues for a period of time and liberate radiation. However, unlike other sources of ionizing radiation with a source of external radiation, nuclear studies represent a source of internal radiation. These studies are of special importance for identifying the function of organs such as the differential renal function which especially important in children with congenital renal anomalies. The ICRP reported a total of 18 million nuclear studies in the United States in 2006. Furthermore, the doubling of ionizing radiation exposure in United States over the last two decades was largely attributable to increased imaging from CT, interventional fluoroscopy, and nuclear medicine [26]. According to the US NCRP, CT scans, fluoroscopy-guided procedures, and nuclear medicine studies represent approximately 26% of the annual imaging procedures. Nonetheless, they cause 89% of the total annual radiation exposure [1, 26].

### Interventional imaging

The main interventional endourologic procedures such as SWL, ureteroscopy, and PCNL use fluoroscopic guidance. The increase in the number of these procedures over the past few decades has raised concerns regarding the amount of radiation exposure associated with these interventions. For example, in the United States, per-capita radiation exposure from medical sources increased about 600% (from 0.54 to 3.0 mSv) between 1982 and 2006 [25]. In terms of radiation exposure associated with each procedure, a study by Safak et al. found a mean ERD of 9.2 mSv (0.82–26.0 mSv) for PCNL [58]. These results were similar to the mean ERD reported by the Mancini group (9.09 mSv) [59]. Higher ERD was associated with higher BMI, larger stone burden, non-branched stone configuration, and higher number of percutaneous access (PCA) tracts [59]. Furthermore, increased stone burden, prolonged operative time, multiple access tracts, and blood loss >250 $cm^3$ have been associated with significantly prolonged fluoroscopy time (FT) [60, 61]. Concerning ureteroscopy, the mean ERD has been recently reported as 1.13 mSv, which is equivalent to that of an abdominopelvic X-ray [62]. This was lower than older studies which reported a mean ERD of 2.5 mSv [63]. The use of recent fluoroscopy devices might explain the cause behind the lower ERD in the more recent study. Predictors of prolonged FT during ureteroscopy were found to be urology trainees, male gender, ureteral balloon dilation, residual stones, use of access sheath, surgeon/trainee behavior, longer duration of the procedure (14 seconds per 10 minutes), and higher BMI [64–66]. Furthermore, the use of flexible ureteroscopes or both flexible and semi-rigid ureteroscopes in the same setting was associated with higher radiation exposure compared with semi-rigid ureteroscopy alone [63]. Regarding SWL, precise stone localization necessitates the use of fluoroscopy. SWL is associated with mean radiation exposure of 1.63 mSv [67]. Higher radiation exposures are associated with higher stone burden, higher BMI, ureteral stones locations, physician inexperience, and higher number of shocks delivered [67–69]. Moreover, radiation is used to follow-up patients with post-SWL. Recently, Kaynar and coworkers evaluated ERD of 129 patients during the first follow-up year following SWL. They reported a mean ERD of 15.91 mSv following SWL of kidney stones, 13.32 mSv following SWL of ureteral stones, and 27.02 mSv following SWL for multiple stone locations. Furthermore, SWL for multiple stone locations was associated with significantly higher radiation exposure during the first follow-up year compared with SWL of solitary renal or ureteral stones [70].

## Occupational radiation exposure for urologists

Until recently, there was paucity in the literature in terms of the amount of radiation to which urologists are exposed and its impact on their health. The 2007 ICRP guidelines recommend 50 mSv (5000 milliroentgen equivalent man or mrem) as an occupational dose limit per year or 100 mSv (10 000 mrem) averaged over 5 years [6]. Furthermore, the United States regulations (Title 10, part 20 of the Code of Federal Regulations) mandate a yearly accepted limit of 5000 mrem as deep-dose equivalent, 15 000 mrem as lens dose equivalent, and 50 000 mrem as shallow-dose equivalent. To ensure practitioners are within these guidelines, there exists a need for a controlled measurement of radiation exposure experienced by practicing urologists over a period of time. Therefore, urologists are recommended using a dosimeter to monitor their radiation exposure. A single-center prospective German study measured the radiation exposure in 12 urologists by placing two thermoluminescent dosimeters (one on the forehead and the other on the ring finger). A total of 188 patients underwent 235 endourologic procedures including 51 ureteral stent changes (USCs), 67 ureteral stent placements (USPs), 67 percutaneous stent changes (PSCs), 39 ureteroscopies, and 11 PCNLs. The authors recorded an average value of 0.04 mSv during USP and USC, 0.03 mSv during PSC, 0.18 mSv during PCNL, and 0.1 mSv during ureteroscopy using the forehead dosimeter and average values of 0.13, 0.21, 0.20, 4.36, and 0.15 mSv during USP, USC, PSC, PCNL, and ureteroscopy, respectively using a dosimeter positioned at the ring finger [71]. Furthermore, a study from North America measured the fluoroscopic radiation exposure of an experienced urologist over 9 months using a thermoluminscent dosimeter installed outside the thyroid shield. The total radiation exposure over 9 months was 87 mrems deep-dose equivalent, 293 mrem lens dose equivalent, and 282 mrem for shallow-dose equivalent [72]. Therefore, these studies showed that radiation exposure for urologists was below the annual accepted limits. Nevertheless, radiation safety protocols and recommendations should be followed to guard against the potential hazards from ionizing radiation.

## Dose-reduction strategies

Over the past two decades, reports have highlighted the increasing use of radiation in medicine. During 2000, a report from the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) found that radiation used for medical purposes accounts for more than 95% of human-made radiation exposure. Furthermore, radiological diagnostic procedures equaled or exceeded one per each individual of the population per year. It has been reported that a person who lives in United States is exposed yearly to an average of 6.2 mSv radiation from ambient sources such as cosmic rays, radon, and medical procedures [73]. While the recommended occupational radiation exposure to medical personnel should be limited to 50 mSv/year, there is no dose threshold for developing stochastic hazards [73]. According to the linear-no-threshold model (or LNT), which is used to quantify radiation exposure and set the regulatory limits for radiation protection, there is no safe dose of radiation and cancer can occur in 1/1000 individuals following exposure to an effective dose as low as 10 mSv [74]. This is because some organs such as the gonads and the eyes are more sensitive than others, such as the extremities. Thus the recommended exposure limits vary according to the body part. In addition, there are variations in radiation exposure among healthcare centers in terms of ERD for the same diagnostic procedure [75]. According to a study by Smith-Bindman and colleagues, there were wide variations among radiation doses reported for different types of medical imaging studies. For example, a mean 13-fold variation was reported between the lowest and highest dose of CT scans for adult patients across and within institutions in the San Francisco Bay area [22]. Therefore, different groups including the American Association of Physicists in Medicine, the American College of Radiology, and NCRP, together with the US Food and Drug Administration (FDA), have worked to establish nationally recognized diagnostic reference levels (DRLs) for different imaging procedures [76]. The ICRP recommended three basic principles for reducing radiation exposure. First is the *principle of justification*, which is defined as "Any decision that alters the radiation exposure situation should do more good than harm," refers to avoidance of unnecessary studies and replacing procedures associated with higher radiation with others that may play the same role, whenever appropriate. Second is the *principle of optimization*, which is defined as "The likelihood of incurring exposure, the number of people exposed, and the magnitude of their individual doses should all be kept as low as reasonably achievable (ALARA), taking into account economic and societal factors," entails performing the diagnostic or interventional procedure with an acceptable quality and lowest radiation exposure. Third, *Application of dose limits*, is defined as "The total dose to any individual from regulated sources in planned exposure situations other than medical exposure of patients should not exceed the appropriate limits specified by the Commission" [6].

## Principle of justification

Justification is a key principle for radiation safety during diagnosis and treatment using ionizing radiation. It entails several items that should be addressed. First, it is mandatory that any ionizing radiation examination prescribed by the referring clinician is required for an individual patient and that the examination has a specific objective, is risk-effective, reliable, and anticipated to influence the decision-making, patient treatment, and final outcome, and that the necessary information cannot be obtained by other modalities with lower risk. Furthermore, a single person should be responsible for the examination and this person is normally a radiologist who is trained in radiological techniques and radiological protection as certified by a competent authority. In addition, a documented request including patient's clinical information, signed or endorsed by a referring clinician, should be available before an examination is performed. In the case of a female patient in the childbearing period the potential that she may be pregnant should always be kept in mind and date of the last menstrual period should be documented and pregnancy test should be ordered in case of doubt in pregnancy [8, 77]. Furthermore, all biomedical research projects that involve the use of ionizing radiation should be institutionally approved by ethics review boards and radiation protection committees.

## Principle of optimization

Following justification of the examination or the image-guided intervention, optimization is the next step towards radiation protection. Optimization of protection is considered a forward-looking iterative process directed to performing the procedure with an acceptable quality while keeping radiation exposure as low as reasonably achievable (ALARA). It takes into account both technical and socioeconomic factors. Therefore, it is a process of "frame of mind" that always questions whether all that is reasonable has been done to reduce doses. The concept of ALARA or "as low as reasonably achievable" was described as a fundamental part of the optimization process. The basis of ALARA principles is that these measures have been compiled to minimize radiation exposure. They are cost-effective to increase compliance. They do not cause unnecessary delay to procedure, do not hinder the performance nor affect the outcome of the procedure. The three basic principles for ALARA are time, distance, and shielding.

### ALARA principles

#### *Time (minimize time)*

One of the most effective methods to reduce radiation exposure to patients and healthcare personnel is to limit the time of radiation exposure. This is particularly important during fluoroscopy where shortening of the FT leads to substantial decrease in radiation exposure. This could be achieved by multiple avenues. (i) Substitute fluoroscopy with other imaging modalities such as ultrasound-guided PCA during PCNL or totally ultrasound-guided PCNL. (ii) Use digital fluoroscopy. (iii) Use "last-image-hold" technology which has been shown to reduce radiation exposure dose by almost 10-fold (from 3000 to 400 mGy). (iv) Use pulsed fluoroscopy with fewer frames per second (such as 1 or 4 frames per second) rather than standard fluoroscopy at 30 frames per second. (v) Fluoroscopy should be turned on/off by the surgeon only during absolute key points rather than continuous stretches. (vi) Keep tracking the FT. (vii) Document the FT after each procedure [78–82] (Box 2.1).

#### *Distance (maximize distance)*

Increasing the distance is considered the cheapest and most effective way to reduce radiation to operating room personnel. It is of particular importance for healthcare

**Box 2.1 Take-home messages in radiation safety measures.**

| | |
|---|---|
| 1 | Practice ALARA principles (minimize time, maximize distance, and always use shields). |
| 2 | Use modern equipment with digital fluoroscopy with last-image hold technology. |
| 3 | Stand as far as possible from the patient to avoid scattered radiation. |
| 4 | Place the image intensifier as close as possible to the patient to minimize scatter radiation. |
| 5 | Minimize the area of radiation exposure by using collimators to narrow the field. |
| 6 | Use pulsed fluoroscopy with 4 frames per second. |
| 7 | Control the foot pedal and movement of the C-arm. |
| 8 | Limit the time of fluoroscopic exposure to a minimum during absolute key points rather than continuous stretches. |
| 9 | Track and document the amount of radiation used for each procedure. |
| 10 | Check each fluoroscopy unit annually. |
| 11 | Invest in custom-made lightweight aprons and examine each apron annually for defects. |
| 12 | Whenever possible, order imaging studies associated with lower radiation exposure such as ultrasound/KUB or low-dose CT. |

personnel. As radiation exposure has an inverse relationship with the square of the distance, doubling the distance reduces radiation to one-quarter and at a distance of 3 m the radiation dose becomes similar to background levels. Healthcare providers can increase the distance by avoiding being in the room during the procedure, whenever possible such as when performing kidney–ureter–bladder (KUB) plain radiographs, intravenous pyelography, or computed tomography (CT). Also, the use of lens-mounted video cameras decreases the distance of the surgeon from the radiation source [7, 82] (Box 2.1).

***Shielding (always use shields)***

Shielding is the third line of defense, especially for personnel who have to be in the radiation field. Shielding is made of heavy metals, most commonly lead which is capable of attenuating radiation. Examples of shields are lead-impregnated eye glasses, gloves, thyroid shields, chest and pelvic aprons, and ceiling-mounted shields. Lead aprons vary in thickness; most are 0.5 mm lead equivalent that attenuate radiation by 96.5–99.5%. Thus shielding does not provide 100% protection from radiation. Therefore, it should not be considered a substitute for other principles of ALARA [7, 83]. Lead aprons should be inspected annually for cracks. In one study, thyroid shields were found to decrease radiation exposure 23 times (from 46 to 0.02 mSv), thereby reducing radiation exposure to background levels [84]. Despite the major benefits of shielding in reducing radiation exposure, the weight of chest and pelvic aprons are associated with orthopedic problems. In 2011, Elkoushy and Andonian surveyed compliance with radiation safety measures and the prevalence of orthopedic complaints among members of the Endourological Society. Almost 64% of respondents reported orthopedic complaints in the form of back problems in 38.1%, neck problems in 27.6%, hand problems in 17.2%, and hip and knee problems in 14.2% [85]. Although there was good compliance (97%) in wearing chest and pelvic aprons, compliance with thyroid shields was only 68%. In addition, only 34.3% of respondents used dosimeters, 17.2% used lead-impregnated glasses, and 9.7% used lead-impregnated gloves [85]. Similarly, other national and international surveys have shown the lack of radiation exposure monitoring in the United States, Europe, India, Brazil, and Turkey [86–89]. Therefore, all of those studies recommended regular radiation safety courses for trainees and urologists. Radiation safety courses have been successful in reducing radiation dose with the implementation of a "radiation awareness program," where focus was placed on taking fewer "snapshots" during SWL [90]. In another study, after implementing a radiation safety education initiative, a significant decrease in dose area product and FT was achieved during pediatric procedures [82, 91] (Box 2.1).

## Principle of application of dose limits

This limit entails that the effective dose or the equivalent dose values prescribed to individuals should not be exceeded during planned exposure situations. This applies only during occupational exposure. For example, the dose limit for a surgeon or the technician should not exceed 50 mSv per year. However, limiting the dose to individual patients is not recommended because it may impact the effectiveness of the patient's diagnosis or treatment. For example, dose limits cannot be applied for patients undergoing radiotherapy, where a target is needed irrespective of the dose of radiation. Therefore, for patients, only the principles of justification and optimization apply [6]. During 2010, the FDA launched a collaborative initiative aimed at reducing unnecessary radiation exposure from medical imaging. This initiative focused on CT, fluoroscopy, and nuclear medicine as the three medical imaging modalities that are associated with highest radiation [1]. The measures included promotion of safe use of medical imaging devices through (i) establishing requirements for manufacturers of CT and fluoroscopic devices to include additional safeguards into the equipment design and developing nationwide recognized DRLs, (ii) supporting informed clinical decision making by adding requirements for manufacturers of fluoroscopy and CT devices to record radiation dose information for use in patient medical records; this may allow the physician together with the patient and the radiologist to further justify procedures which necessitate ionizing radiation, and (iii) increase patient awareness and provide them with tools to track their personal medical imaging history such as using a patient medical imaging record card [1].

During 2014, the government of Germany hosted an international conference sponsored by the International Atomic Energy Agency and the World Health Organization calling for action on radiation protection in medicine in the next decade. This conference was coined the “Bonn Call for Action” [92]. The conference recommended 10 main actions: (i) enhancing the implementation of the principle of justification by applying the 3 As (awareness, appropriateness, and audit), (ii) enhancing the implementation of the principle of optimization by ensuing the use of the DRLs for imaging procedures and strengthening the establishment of quality assurance programs for medical exposure, (iii) strengthening the manufacturers’ role in contributing to the overall safety regime, (iv) strengthening radiation protection education, (v) shaping and promoting a strategic research agenda for medical radiation protection, (vi) increasing the availability of information on medical exposure, (vii) improving the prevention of medical radiation accidents and incidents, (viii) provoking the radiation safety culture in healthcare, (ix) fostering an improved radiation risk-benefit dialogue among health professionals, patients, and the public, and (x) strengthening global implementation of radiation safety requirements [92].

## Dose-reduction strategies during diagnosis

While CT is considered the workhorse in evaluation of most non-emergent and emergent medical situations, it is the imaging modality that is associated with highest potential for radiation exposure (Table 2.1) [13, 14, 93]. Therefore, it constitutes a major concern for healthcare professionals and patients especially those who are recurrent stone-formers and are at risk of undergoing repeated CTs with the associated risks of cumulative radiation exposure [14, 56, 94, 95]. Katz et al. reported a cumulative radiation dose associated with repeated CT scans between 8.5 and 154 mSv [96]. Furthermore, reports by NRCP reported a yearly increase in the number of CTs performed in the United States of about 10% between 1993 to 2006 with estimated 62 million CT examinations performed during 2006 alone [2]. Given the importance of CT as a first-line choice for diagnosis of different urological diseases especially stone disease, and the potential hazards of the high doses of radiation associated with CT, several strategies were proposed for lowering radiation exposure. These strategies depend on either modifying the basic design of scanners and their components or the technical parameters such as slice thickness, pitch, and tube current modulation. In addition, appropriate patient centering on the gantry has been reported to decrease the dose by 20% by decreasing *z*-axis coverage. Pitch is the speed at which the table moves through the scanner gantry and increasing pitch results in radiation dose reduction. In a study by McCollough and colleagues, increasing the pitch from a standard of 1 to 1.5 resulted in 33% reduction in effective dose while still maintaining adequate image quality from a single-slice helical CT [97]. However, these results could not be achieved with multi-slice CT [98].

Furthermore, optimization of slice thickness was accompanied by reduction in radiation dose without compromising diagnostic accuracy. While slices at 0.5 mm detected stones at 70% higher than slices at 5 mm, it was associated with significantly higher radiation exposure in single-detector CT scanners [99]. Therefore, optimization of slices at 2.5 mm was proposed and it would detect most clinically relevant stones with single-detector CT scanners. However, the latest

**Table 2.1** Effective dose associated with different imaging and image-guided interventions.

| Procedure | Mean effective dose (mSv) |
|---|---|
| KUB [24, 55, 94, 111] | 0.7–1.1 |
| IVU [24, 55, 94, 111] | 1.5–3.5 |
| Standard-dose CT, abdomen [24, 55, 95] | 5–10 |
| Standard-dose CT, pelvis [55, 95] | 5–10 |
| Standard-dose CT, urogram [22, 24] | 10–31 |
| Low-dose CT, abdomen/pelvis [94, 102] | 2.0–3.5 |

multi-detector CT (MDCT) scanners presented the possibility of decreasing the slice thickness without increasing radiation exposure. For example, there was no change in radiation dose among different slice thicknesses using the 64-MDCT scanner [100]. Furthermore, radiation exposure could be further decreased while maintaining an appropriate image quality by obtaining slices of 5 mm and complementing it with 3 mm coronal/sagittal reformatted images [34, 35].

Reducing the tube current has been found to be the most effective method of reducing radiation exposure. There is linear relationship between radiation dose and tube current. Therefore, a 50% reduction in tube current leads to a 50% reduction in the radiation dose. The tube current can be adjusted either manually using manual selection of a lower fixed tube current or automatically using automatic tube current modulation, optimizing the dose according to the density of tissues penetrated by radiation and patient body habitus. This could be achieved by incorporating software that uses the scout image to make adjustments in radiation output according to the patient's BMI and the tissues examined. However, reduction in tube current results in increased "noise," which is acceptable in certain situations such as stone disease. These recommendations are based on several studies that showed comparable accuracy between low-dose CT (LDCT) and standard-dose CT (SDCT) in detection of renal calculi. In one study, simulated CT reconstructions at 50 and 75% reductions from the original dose had comparable sensitivities compared with the SDCT in detection of stones >3 mm [101]. In another study by Polletti and coworkers, the accuracy in detecting ureteral calculi was comparable between LDCT and SDCT in patients with a BMI of less than 30 kg/m$^2$ with significant reduction in radiation exposure (9.6 vs. 1.6 mSv in men and 12.6 vs. 2.1 mSv in women). However, in patients with a BMI of ≥30 kg/m$^2$, the sensitivity of LDCT to detect ureteral calculi was only 50% [102]. In addition, according to a recent systematic review, LDCT scans resulted in radiation exposure ranging from 0.5 to 2.8 mSv, and had a sensitivity of 90–97% and a specificity of 86–100% for diagnosing stone disease. However, this technique may miss small ureteral stones (<3 mm), especially in obese patients (BMI >30 kg/m$^2$) [103]. Several studies confirmed the lower accuracy of LDCT for detection of ureteral calculi in obese patients [102, 104, 105].

Since 1998, MDCT scanners have been used in diagnosis and planning of treatment for patients with renal stones. It has the ability to perform three-dimensional reconstructions and multi-planar reformatting while obtaining slices down to 1 mm thick [34, 35]. In one study, using a 16-MDCT with tube current modulation, there was comparable accuracy between LDCT and SDCT in detection of urolithiasis in both non-obese and obese patients [106]. While LDCT using MDCTs was associated with relatively higher radiation dose (1.41 mSv), this radiation dose was still significantly lower than the SDCT (2.89 mSv) [106]. Furthermore, the positive correlation which was noted between ERD and BMI ($r$=0.86) was congruent with the hypothesis that radiation exposure is higher in obese patients [106]. In a recent study by Abou El-Ghar and colleagues, the use of automatic tube current modulation that is available in modern multi-slice CT scanners such as 64-MDCT made it possible to use LDCT with comparable results to SDCT even in obese patients [107]. Moreover, employing LDCT was equally sensitive to SDCT in detecting uric acid stones at very low radiation doses. Therefore, ultra-low dose protocols have demonstrated a high sensitivity and specificity (97 and 95%, respectively) in detecting calculi while reducing radiation exposure [37, 108, 109]. In a meta-analysis by Niemann and colleagues, LDCT reported to detect urolithiasis with a sensitivity of 97% and specificity of 95% [32]. Therefore, LDCT should be preferred to SDCT and be considered the first-line imaging modality in acute renal colic [32]. Based on these data, LDCT is now recommended by the American and European Urological Association guidelines as the first-line imaging modality for evaluation of non-obese (BMI <30 kg/m$^2$) patients who present with renal colic [110, 111]. Despite these recommendations for LDCT, a recent study evaluating CT studies for patients presenting with renal colic to 93 institutions in the United States demonstrated that only 2% of CTs were performed using LDCT protocols [112].

Radiation exposure could be further reduced using iterative reconstruction technology, where CT scans can be performed with lower current and lower kVp [113].

Recently, multiple iterative image reconstruction methods have been developed by almost all CT manufacturers for reducing radiation dose without sacrificing image quality. These include iterative reconstruction in image space (IRIS) by Siemens Medical Solutions, adaptive statistical iterative reconstruction (ASIR) and model-based iterative reconstruction (MBIR) by GE Healthcare, iDose by Philips Healthcare, and adaptive iterative dose reduction (IARD) by Toshiba Medical Systems. While ASIR reduces the radiation dose by 32–65% without increasing noise in the reconstructed images [114], MBIR was found to improve the spatial resolution and reduce the noise of the obtained CT images at the same time [115]. However, ASIR is much faster than MBIR. Despite the lack of published data on IRIS, IARD, and iDose, information from manufacturers suggests the potential for decreasing radiation dose in the range of 30–60%. A recent study employing ASIR reported the feasibility of performing low-dose CT scan in patients with renal colic using radiation dose equivalent to KUBs [116]. The authors found that LDCT with 70% ASIR had a sensitivity of 87% and specificity of 100% for detection of calculi of >3 mm and was associated with significantly lower radiation exposure compared with the SDCT (0.48±0.07 vs. 4.43±3.14 mSv; $P < 0.001$) [116].

The latest “digital tomosynthesis” (DT) technology is based on conventional X-ray tomography where a series of low-dose projection images are obtained with a digital detector during a single sweep of the X-ray tube. Using special software, the data are then reconstructed in a way that can provide in-depth information about the structures of interest [117]. This technology was primarily used for imaging of the chest and breast [118].

Mermuys and colleagues reported the superiority of DT compared with digital radiography for the identification of renal stones [119]. However, there was no difference between the two modalities for detection of ureteral stones. Furthermore, Wells and coworkers studied the diagnostic quality of the traditional IVU compared with DT-IVU. They found that DT-IVU was associated with better diagnostic accuracy (95.5 vs. 46.5%) and less radiation exposure compared with the traditional IVU [120]. A recent study by Astroza et al. compared the ERD of radiation accompanying KUB, IVU, stone protocol NCCT, and DT during follow-up of patients with urolithiasis [118]. They reported an ERD of 0.63 mSv with KUB, 3.93 mSv with IVU, 3.04 mSv with stone protocol NCCT, and 0.83 mSv with DT [118]. However, compared with traditional CT, DT has difficulty in identifying ureteral stones and small stones (<2 mm). Therefore, it should not be considered as a substitute for NCCT in either the evaluation of renal colic patients or the planning for surgery. Nevertheless, it provides more information when compared with KUB and it is associated with less radiation exposure than stone protocol NCCT with comparable costs. Therefore, it might be a valuable imaging modality in the follow-up of recurrent stone-formers [118].

Finally, two studies compared the diagnostic accuracy of combined ultrasound and KUB with CT in patients presenting with renal colic and reported lower sensitivity of the combined ultrasound and KUB compared with CT (79 vs. 93% in one study and 77 vs. 93% in the other) [121, 122]. Therefore, combining ultrasound with KUB would best replace CT in follow-up of patients with clinically significant radiopaque stones either during conservative treatment or in the follow-up after endourologic procedures such as SWL, ureteroscopy, or PCNL. MRI or magnetic resonance urography (MRU) is a technique that produces no ionizing radiation and can be used to evaluate the genitourinary system. MRI previously had a significant role in chronic kidney disease patients where iodinated contrast used in CT or IVU was contraindicated. MRU is now contraindicated in patients with renal impairment secondary to gadolinium’s association with nephrogenic systemic fibrosis. Nevertheless, MRI provides excellent anatomy with accurate delineation of the location and degree of obstruction and presence of perinephric fluid. However, it can’t differentiate stones from blood clots or tumors [123]. In order to overcome this, Blandino and colleagues performed a study using MRU to identify the level of obstruction, then performed targeted CT to determine the cause of obstruction. This protocol was associated with significant reduction in ERD and the sensitivity for detecting urinary stone was 98% [123]. However, this protocol is time-consuming, expensive, and MRU is not readily available. Therefore, it lacks clinical applicability. While most of dose reduction protocols focus on stone disease, patients with malignant diagnoses undergoing surveillance protocols or follow-up imaging would likely benefit from minimizing radiation exposure. The optimal parameters for patients in these situations have yet to be determined but are a potential future research direction.

## Dose reduction strategies during endourologic interventions

According to FDA regulations, all fluoroscopy units should produce similar radiation profiles at settings of a maximum potential energy of 120 kVp and current of 2 mA. Hence, radiation exposure to patients and operating room personnel depends on the operator and the type of the procedure. Generally, there are several strategies to decrease radiation exposure during endourologic interventions such as following ALARA principles, using pulsed fluoroscopy with last-image-hold technology, and collimating the beam to the region of interest.

Here are some specific radiation reduction strategies during the three most common endourologic interventions.

### SWL

Based on its noninvasive nature, few side effects, and excellent stone clearance, the latest guidelines recommend SWL as the cornerstone intervention for management of uncomplicated renal stones <2 cm and proximal ureteral stones <10 mm [124–126]. Radiation exposure during SWL is low [127]. During 50 SWL procedures, the mean FT was 204 seconds and the mean ERD during was 1.63 mSv [67]. Another study found that, SWL of renal stones was associated with higher ERD (7.23 mSV), when compared with ureteroscopy (6 mSv) [128] (Table 2.1). This is because stone localization in most SWL machines depends largely on fluoroscopy. However, it is possible to reduce radiation exposure during SWL without compromising outcomes. Therefore, recommendations to decrease radiation exposure during SWL should be followed to decrease radiation exposure to patients. Several investigations have studied radiation exposure during SWL. For example, the risk of fatal cancer from SWL was estimated to be 140/1 million of patients receiving SWL for proximal ureteral calculi and 85/1 million of patients receiving SWL for distal ureteral calculi [69]. In a study by Griffith and co-investigators, reducing the number of radiographic "snapshots" during SWL was associated with 62% reduction of radiation dose in the most obese patients (from 152 to 95 mGy per procedure) [90]. Others reported a mean skin surface radiation exposure of 178 mGy per procedure in a cohort of 298 SWLs [129].

To further reduce radiation exposure during SWL, several measures has been proposed [130]. These include the use of low-dose fluoroscopy, keeping the image intensifier close to the patient, avoiding fluoroscopy when personnel are close to the unit and when the balloons are deflated, and using intravenous contrast or retrograde pyelography for faintly radiopaque stones [130]. The other important parameter is the operator (technician or urologist) experience. In one study, there was significant impact of a technician's experience on FT and outcome during SWL [131]. Therefore, this may explain the discrepancy in ERD among different studies. Alternatively, ultrasound could be used during the localization process since modern SWL units are equipped with ultrasound guidance. This could be used as an alternative to fluoroscopy to reduce exposure to reduce radiation exposure. However, ultrasound-guided SWL was associated with lower stone-free rates ranging from 37 to 66.5% [132, 133]. Despite these disappointing results, it seems that the advancements in SWL devices incorporating ultrasound-guidance may improve SWL outcomes in the future while avoiding radiation exposure. Recently, the three-dimensional ultrasound stone locking system was found to reduce radiation exposure during SWL [134]. Abid and colleagues compared a new three-dimensional ultrasound stone locking system (Visio-Track) (EDAP-TMS) with a conventional ultrasound localizing system (Sonolith® i-sys) (EDAP-TMS) in terms of FT, radiation dose, and efficacy of SWL. They reported significantly lower FT (3.5 vs. 159.5 seconds; $P < 0.001$) and radiation dose (163 vs. 10 598 mGy/cm$^2$; $P < 0.001$) associated with significantly higher stone-free status (79.5 vs. 54.5%; $P = 0.001$) with the new three-dimensional ultrasound stone-localizing system compared with the conventional ultrasound stone-localizing device [134]. Therefore, with the latest SWL devices utilizing three-dimensional ultrasound stone-localizing systems it is possible to reduce radiation exposure without compromising outcomes during SWL.

## Ureteroscopy

Ureteroscopy is associated with significantly higher radiation exposure in obese patients [52, 66]. Other predictors of increased radiation exposure during ureteroscopy include renal flexible ureteroscopy when compared with rigid ureteroscopy, prolonged procedural time, postoperative stenting under fluoroscopic guidance, male gender, balloon dilatation of the ureteral orifice, and surgeon experience [64, 65, 135, 136].

To decrease radiation exposure during ureteroscopy, urologists should control the foot pedal and use last-image-hold technology which has been shown to decrease radiation exposure by 40 times (from 100 to 2.5 mSv) [63]. Furthermore, Greene and colleagues found that using physical markers and laser guidance resulted in 82% reduction in FT (86.1 vs. 15.5 seconds; $P < 0.001$) without affecting operative time and procedural outcomes [137]. In addition, using pulsed fluoroscopy at 4 frames/second was associated with 62.4% reduction in FT, when compared with the standard fluoroscopy at 30 frames/second during ureteroscopy (from 109.1 to 44.1 seconds; $P < 0.001$) [81]. Using a validated non-obese male model, these fluoroscopy reduction techniques were shown to decrease the mean FT down to 47 seconds with a median ERD of 1.13 mSv [62]. In order to further decrease FT during ureteroscopy, Hsi and coworkers performed ureteroscopy with only two shots of fluoroscopy to ascertain the proper stent placement bringing the median ERD down to 0.05 mSv [138]. However, a safe "fluoroless" placement of the ureteral stent following ureteroscopy was described a year prior to the Hsi et al. study [139]. Another modification in the technique was the description of radiation-free ureteroscopy or "fluoroless ureteroscopy" [140–142]. This technique entails performing ureteroscopy without the use of any source of imaging, but rather depends on visual and tactile cues. In one study, the authors were able to extract distal ureteral calculi in a fluoroless manner in 99/110 patients [140]. Others, reported the feasibility of performing fluoroless ureteroscopy in 92% of their cohort (86/92 patients) [141]. In order to avoid radiation exposure from fluoroscopic-guided ureteroscopy, other groups proposed ultrasound-guided ureteroscopy [143, 144]. This technique basically uses ultrasound to confirm the position of the ureteral stent and the guidewire. In a level 1 evidence study, the procedural outcomes during ultrasound-guided ureteroscopy were comparable with fluoroscopic-guided ureteroscopy for extracting ureteral stones <8 mm [144]. While this technique was successful in expert hands, it has limitations such as the lack of familiarity of most urologists with ultrasound and the challenge of using ultrasound guidance in obese patients.

### PCNL

The latest American Urological Association guidelines on staghorn stones recommend fluoroscopic-guided PCNL as the first-line option for treatment of large renal stones [41]. However, compared with other endourological procedures, PCNL was associated with the highest radiation exposure [7, 145–147]. Furthermore, morbidly obese patients and patients with large stone burden that necessitates multiple access tracts are even at higher risk of radiation during PCNL [59, 62]. It has been reported that, during PCNL, patients are exposed to a radiation dose similar to that during a NCCT of the abdomen or pelvis [62]. Given these findings, a patient undergoing PCNL will receive radiation during preoperative CT scan, intraoperative fluoroscopy equaling another CT scan, and a postoperative follow-up CT scan. This makes the patient at risk of receiving radiation comparable to the 50th percentile of the dose received by the victims of the Hiroshima and Nagasaki nuclear bombs in World War 2 [62, 148]. Thus PCNL patients are at a potential risk of the stochastic consequences of radiation resulting from exposure to excessive ionizing radiation [14, 20, 149, 150]. Therefore, several investigators looked at the predictors of radiation exposure during PCNL to determine factors associated with prolonged FT and ERD [59, 61, 141]. In addition, different scoring systems were introduced and validated with the aim of assessing of PCNL complexity preoperatively [27, 151–155]. Recent studies did not find significant effects of PCNL complexity on FT [156, 157].

There are several strategies for reducing radiation exposure during PCNL. For example, our group reported a significant reduction of FT during PCNL when using pulsed fluoroscopy at 4 frames/second compared with using standard fluoroscopy at 30 frames/second. This simple technique was associated with 65% reduction in FT (from 341.1 to 121.5 seconds; $P < 0.001$) [81]. Furthermore, the use of a laser-guided C-arm with fixed lower current and kVp in addition to an experienced radiology technician and pulsed fluoroscopy at 1 frame/second was associated with more than 80% reduction in FT during PCNLs (from 175.6 to 33.7 seconds) [158]. Another technique is air pyelography, which halved the mean adjusted ERD from 7.67 to 4.45 mSv [159]. Others performed percutaneous renal access under endoscopic guidance. Endoscopic-guided PCNL is a technique where the PCA is obtained using assistance via retrograde flexible ureterorenoscopy [160]. It has been shown to be associated with advantages of fewer access tracts, lower transfusion rates, and shorter operative times [161–163]. A study by Lantz et al. reported that endoscopic-guided PCNL was associated with significantly lower FT and ERD compared with standard PCNL [164]. This is because establishment of PCA contributes the most to FT during PCNL. With the presence of a pre-formed PCA is associated with a significant reduction in FT during PCNL [165]. A study by the Clinical Research Office of Endourological Society (CROES) included 5806 patients treated with PCNL to compare perioperative outcomes of PCNL using either ultrasound or fluoroscopic guidance for PCA. They compared a matched sample of 453 patients in each group. On multivariate analysis, they did not find significant difference between outcomes of both groups in terms of stone-free rates and complications [166]. Therefore, it is logical that ultrasound-guided PCA significantly reduced FT and subsequently radiation exposure during PCNL [167]. Another study confirmed that totally ultrasound-guided PCNL was feasible with comparable outcomes to fluoroscopic-guided PCNL [168, 169]. In addition, both techniques were equally feasible and safe in the hands of postgraduate trainees with comparable outcomes and significantly lower radiation exposure in the ultrasound-guided PCNL [170]. However, the lack of familiarity of most North American urologists with ultrasound guidance and lack of availability of ultrasound machines with abdominal probes may limit the applicability of this procedure. Furthermore, it may be difficult in obese patients. Others reported some success with blind access without imaging assistance. In a level 1 evidence study by Basiri and co-investigators, 50/100 patients were randomized to blind-access PCNL, when up to five punctures were attempted before fluoroscopy [171]. PCNL procedures were completed with 50% success when access was obtained blindly compared with 90% success when access was obtained with fluoroscopic guidance. In terms of outcomes, blind access was associated with more procedural time (6.6 vs. 5.5 minutes, $P < 0.01$) and lower stone-free rate (62 vs. 100%). Nonetheless, blind access was performed without the need for fluoroscopy. This approach may be reserved in case of unavailability of ultrasound and should only be performed by expert hands in certain cases [171].

## Radiation exposure during brachytherapy

Brachytherapy is an established treatment option for organ-confined, low-grade prostatic adenocarcinoma. It is a sort of internal radiation therapy that is applied for the prostate at either low dose rate using implantation seeds or high dose rate. The aim is to place radiation close to cancer cells, where the radiation can kill the cancer cells without producing marked damage to nearby healthy tissues. Temporary brachytherapy entails placing radioactive wires within the prostate gland close to the tumor for several minutes before these wires are removed. While permanent brachytherapy includes placing radioactive seeds permanently within the prostate, where they slowly release radiation. It is usually performed in collaboration with a radiation technologist and radiation oncologist. The amount of radiation exposure depends on whether the procedure is performed under ultrasound or fluoroscopic guidance (usually less than 100 mSv/minute) and on the radioactive isotope being used. For example, $^{192}$iridium has a long half-life of 74.2 days and produces an average energy level of 380 KeV [172]. Others have shorter half-lives such as $^{125}$iodine, which has half-life of 60.2 days and produces energy level of 28 KeV, and $^{103}$palladium which has a half-life of 17 days and produces energy level of 21 KeV. Brachytherapy was previously performed through an open wound; thus the surgeon's hands were receiving most of the radiation exposure at an annual rate of 18.7 mGy [173]. Recently, the amount of radiation exposure has decreased with the use of ultrasound-guided percutaneous needle placement of radioactive isotopes. However, it is important to follow the local applicable regulations for radioactive materials to minimize handling of radioactive seeds and place them in labeled metallic containers [174].

## Virtual reality simulator training and radiation exposure

The learning curve of PCNL is quite long. It is reported that 36–45 cases are needed to achieve competency and 105–115 to achieve proficiency [175, 176]. Recently, the use of virtual reality simulators for training was associated with significant decrease in radiation exposure while obtaining the percutaneous renal access. Noureldin et al. found that trainees with prior PCA experience performed better on the PERC Mentor™ simulator with significantly lower FT [177, 178]. Furthermore, Papatsoris and colleagues reported significant reduction in the FT during PCA in trainees who received training on the PERC Mentor simulator (Symbionix, Cleveland, OH, USA) compared with trainees who did not receive training (6.49 vs. 15.8 minutes; $P < 0.01$) [179]. Therefore, virtual reality simulators could be used to train urologists in obtaining PCA leading to significant reduction in radiation exposure to both patients and urologists during the early phase of the learning curve [177, 178].

## Radiation reduction strategies in special circumstances

### Pediatric urology practice

When using radiation for diagnostic or interventional purposes, it must be noted that age of the patient is important to keep in mind. This is because infants and children are at higher risk of developing cancer compared with adults receiving the same dose of radiation. There are two reasons for this: (i) the developing tissues and organs are more sensitive to the effects of radiation and (ii) infants and children have a longer expected life expectancy which gives more time for any hazards of radiation to manifest. Therefore, it is widely recognized that pediatric patients must be treated differently compared with their adult counterparts [8, 148]. Furthermore, it has been reported that approximately 25% of radiation exposure in children arises from imaging of the urinary system [180]. Therefore, during 2013, the ICRP introduced *Publication 121* to highlight "radiological protection in pediatric diagnostic and interventional radiology" [8]. It reinforced the importance of justification of imaging procedures which utilize ionizing radiation and ascertained the importance of adjusting the equipment for pediatric patients and optimizing radiation protection to significantly improve radiological protection and deliver significantly lower doses to pediatric patients [8]. This could be achieved by purchasing new imaging equipment with available dose reduction measures. In addition, special attention should be given to the unique aspects of pediatric imaging such as the wide range in patients' weight which require modification of equipment, technique, and imaging parameters. Furthermore, attention should be paid to the patient's position, field size, adequate collimation, use of protective shielding, optimization of exposure factors, use of pulsed fluoroscopy, limiting FT, and sticking to the acceptable DRLs in pediatric population. Moreover, pediatric interventional procedures should be performed by experienced hands with a specific level of training in radiological protection.

#### CT

It has been reported that 7–10% of CTs are performed for children [21]. An epidemiological study by Pearce and coworkers including a cohort of 178 604 children who underwent CT scan between 1985 and 2002 in different hospitals in the United Kingdom with average follow-up of about 10 years. They found that children who received CT scans had higher incidence of brain cancer and leukemia [181]. Furthermore, they found a significant association between the estimated radiation doses delivered by CT scans to the brain and the red bone marrow and the risk of brain tumors and leukemia, respectively. Having two or three head CT scans put the child at three times the estimated risk of brain cancer, while 5 to 10 head CT scans put the child at three times estimated risk of leukemia [181]. However, a recent multi-center cohort study including 67 274 children who had their first CT scan before the age of 10 years during the period between 2000 and 2010 questioned whether this reported increase in cancer risk in children was biased by the indications for CT scans [182]. Over a mean follow-up of 4 years, 73 cases were diagnosed with cancer, 27 with central nervous system tumors, 25 with leukemia, and 21 with lymphoma. However, 32% of children diagnosed with cancer were among those with predisposing factors. Following adjustment for predisposing factors, the excess cancer risk estimates related to cumulative doses from CT scans were reduced. Therefore, Journy and colleagues recommended that the indication for examinations, whether for predisposing factor management or suspected cancer, should be considered to avoid overestimation of the cancer risks associated with CT scans [182].

One study suggests that up to one-third of all CT scans in pediatric populations could be eliminated or replaced by alternative approaches [183]. This highlights the importance of justification on lowering pediatric radiation exposure. Furthermore, optimization of radiation protection is critical when performing CT in the pediatric population. This could be achieved by adjusting the scan parameters such as current, kVp, and pitch according to the patient's weight, age, scanned region, and study indication. Other optimization strategies include scanning only the area in question with avoidance of overlapping of scan regions, restricting multi-phase examination protocols, and the use of the state-of-the-art reduction technology such as tube current modulation, organ-based dose modulation, auto kV technology, and iterative reconstruction technology [184].

#### Voiding cystourethrography

Fluoroscopic voiding cystourethrography (VCUG) with spot films is considered the gold standard for diagnosis and grading of vesicoureteral reflux due to its acceptable sensitivity and negative predictive value [185]. Although it is associated with lower amount of ionizing radiation delivered to a child compared with other commonly performed pediatric examinations such as CT, ALARA principles recommend that radiation exposure during VCUG should be kept to minimum as children possess growing tissues and organs that are about 10 times more sensitive to ionizing radiation than adults [186]. As the fluoroscopic dose during VCUG is estimated to be 80% of the entire radiation dose, the use of fluoroscopy with spot films during VCUG was challenged. Recently, Alamdaran and colleagues evaluated the validity and radiation dose reduction using photofluorography with hard copy images compared with fluoroscopic VCUG with spot images. They found that photofluorographic VCUG was comparable to fluoroscopic VCUG in diagnosis and grading of vesicoureteral reflux with a sensitivity of 96% and specificity of 100%. Moreover, it was associated with a 50–90% reduction in radiation exposure [180]. Recently, Linke and colleagues employed an ultra low dose during 651 VCUGs using a modern flat detector. They found that with these new instruments and optimized protocols, VCUG could be performed with significantly lower radiation exposure and without obvious decrease in diagnostic image quality [187].

### Pregnant women

To better understand the hazards of radiation exposure during pregnancy, we will first cover the effects of *in utero* irradiation on the embryo/fetus. These effects are related to the absorbed dose to the embryo/fetus and at which stage of pregnancy. These include (i) lethal effects might occur as a result of radiation exposure during the pre-implantation period of embryonic development, (ii) malformations occur following exposure to a threshold of about 100 mGy during the third to eighth week of gestation which is considered the period of major organogenesis, (iii) the highest sensitivity of the central nervous system to radiation is encountered during the eighth to fifteenth week of gestation with lower sensitivity between the sixteenth and twenty-fifth week; exposure to approximately 1 Gy may cause severe mental retardation, and (iv) cancer development: throughout pregnancy, the fetus is at a potential risk of cancer from radiation exposure that is three times higher than normal populations. Given the aforementioned risks, it is important for pregnant patients to avoid diagnostic or interventional procedures using ionizing radiation and a balance between the health status of the mother and the potential health hazards on the embryo/fetus must be considered [26, 188, 189]. Moreover, there is potential risk for the mother too. Noncontrast MRI and ultrasonography are not associated with ionizing radiation; thus they are not associated with any known adverse fetal effects. However, their sensitivities and specificities in detecting ureteral calculi are low. Furthermore, the use of gadolinium contrast material to differentiate a ureteral stone from a filling defect during pregnancy is contraindicated due to its potential teratogenic effects.

According to the American Congress of Obstetricians and Gynecologists and the American College of Radiology, a single diagnostic X-ray procedure is safe and does not result in adequate radiation exposure that threaten the well-being of the developing embryo or the fetus [190]. Therefore, a KUB is associated with a small amount of radiation and can be safely performed as a diagnostic modality during pregnancy, whenever appropriate. Furthermore, it has been reported that a limited IVU of three or four films delivers around 2–2.5 mGy to the fetus and can be safely performed during pregnancy, whenever urgently needed. However, the lower part of the ureter may be masked by the fetus. Fluoroscopy is associated with considerable radiation exposure to the fetus: 15–20 mGy/minute. Therefore, it is reasonable to use ultrasound as an alternative to fluoroscopy during pregnancy, whenever possible [189]. With recent advances in CT scanners and dose reduction technologies, the use of LDCT in diagnosis of urolithiasis during pregnancy becomes permissable [191]. In a study by Johnson et al., 46 ureteroscopies were performed in 45 pregnant females at five different tertiary care institutions [192]. Imaging modalities used for preoperative assessment of the patients varied according to the center and surgeon preference. CT was accurate in detecting 95% of stones. However, ultrasound and MRI showed lower accuracies (72 and 80%, respectively) [192]. While some patients in this study underwent CT for diagnosis, there were no fetal losses. However, we do not know what happened to the delivered children afterwards. Nonetheless, the use of CT with recent techniques such as ultra-low dose with iterative technologies that significantly decrease the ERD while maintaining high sensitivity and specificity of ureteral stones may play an important role in the near future.

Regarding endourologic procedures, ureteroscopy has been shown to be safe during pregnancy with the advantage of definitive management by removing the obstructing stones rather than inserting ureteral stents or nephrostomy tubes with the need for frequent changes during pregnancy [193–196]. In 2002, Watterson and co-investigators reported the safety and efficacy of ureteroscopy and holmium laser lithotripsy in eight pregnant patients. Ninety-one percent of the procedures were successfully completed with an overall stone-free rate of 89% [193]. Half of these cases necessitated the use of fluoroscopy with an average FT of 0.19 minute while the area of the fetus and the contralateral kidney were covered with lead shields. Others reported similar outcomes in 45 patients who underwent 46 ureteroscopies during pregnancy in five tertiary care centres [192]. The most common obstetric complication was preterm labor, which may be managed conservatively without fetal loss. Others reported the feasibility of rigid ureteroscopy without the need for ureteral dilation during pregnancy [197]. In a systemic meta-analysis there was no significant difference in the outcomes of ureterosopy in pregnant and nonpregnant patients in terms of ureteral injury (0.9 vs. 3.8%) or postprocedural urinary tract infection (4.6 vs. 3.8%). However, premature uterine contractions were reported in 0.9% of pregnant females who underwent ureteroscopy and this was resolved by tocolytics [198]. Three years later, a meta-anlaysis on 116 ureteroscopic procedures in pregnant women showed similar results with 86% success rate and two major complications (one case of premature uterine contraction and one ureteral perforation) and seven minor complications (two cases of postoperative pain and five cases of postoperative urinary tract infections) [196]. Few case reports refer to the possibility of performing PCNL during the first trimester using ultrasound guidance and the second trimester of pregnancy employing strict techniques to reduce fluoroscopy with proper shielding [199]. However, SWL and PCNL remain contraindicated during pregnancy by international guidelines [124, 126].

Video 2.1 outlines radiation safety for urologists.

## Introduction

Innovations and improvements in video imaging technology have paved the way for significant advancements in endourology and minimally invasive urologic surgery. Recent advances in technology have made what once appeared to be science fiction into reality. Augmented reality, three-dimensional (3D) video imaging, photodynamic and fluorescence-enhanced optics, and video image overlay are all being incorporated into current surgical practices. These technologies are not only facilitating the performance of complex surgical procedures but are allowing wider dissemination of the skills needed to perform these procedures. As these technologies continue to develop, their applications in minimally invasive endourological practice will only grow.

This chapter will review the current state of the art of video imaging systems within endourology. Technological advancements and their application in current endourological practice will be discussed. It is anticipated that this information will not only help the reader to enhance their video imaging practices today, but also prepare one for tomorrow's tremendous innovations in advanced imaging modalities.

## Digital imaging

There have been a number of major improvements which have greatly enhanced videoendoscopic surgery [1–3]. These significant advances have been the development of the charge-coupled device (CCD) chip camera and the introduction of digital video imaging. Once an optical image is focused on the CCD chip, there is a conversion of the optical (light) image to an electronic signal [4]. This electronic information, which includes both color and light (luminance), can be scanned by a video monitor to produce an image on the screen.

Standard National Television Systems Committee (NTSC) video signals utilize a limited "band width" which include both the color and luminance information in a single or "composite" signal. Problems with this format include "signal noise," which is caused by the camera having to first process color and luminance information separately and then combine the two pieces of information to create a video signal. This video noise or "crosstalk" may be the cause of decreased resolution, grainy images, and loss of information around the edges of the video image. With the advent of digital imaging, newer video formats have been introduced [5]. The first format allows the color and luminance information to be carried as two separate signals. This "component" video signal is called Y/C (S-video), with Y standing for luminance or light brightness and C referring to color. This component signal contains less crosstalk and therefore appears cleaner and sharper than images generated by composite signals. The video signal in a Y/C format is carried by a single cable, as with the NTSC format, although the color and luminance information are still separated.

Another video format is known as RGB (Red-Green-Blue). This RGB format is also a component signal, yet it is distinct from the Y/C format in that the video information (color and luminance) is separated into four signals. These include a red, green, and blue signal as well as a timing signal. Each individual signal carries its own luminance information. Separation of the video signals is performed electronically in the camera head. The RGB format requires less electronic processing than do the NTSC or Y/C formats since the color and luminance information are separate from the start. Therefore, the RGB image quality is greatly enhanced compared to the

Companion website: www.wiley.com/go/smith/textbookofendourology

other two formats. Also, in contrast to the single-cable NTSC and Y/C formats, the RGB video signal is carried by four separate cables (red, green, blue, and sync). Both Y/C and RGB formats offer superior image quality.

## Standard video systems

The technical advantages created by video monitoring include binocular vision and magnification of the monitor images. Magnification may be as great as 20 times, depending on the initial optics system used. This enlarged image permits better inspection of detail and allows the operator, by virtue of the enlarged image size, to perform the procedure off the monitor rather than looking directly through the endoscope [6]. This approach significantly decreases operator strain because the surgeon no longer needs to conform his body to the angle of the viewing lens. Instead, the urologist can simply attach a video camera to the scope and manipulate the endoscope while standing comfortably and observing the video monitor [3]. Moreover, the upright position assumed by the urologist decreases the likelihood of coming in contact with potentially infected body fluids.

### Video cameras

All video systems are currently composed of a CCD solid-state chip camera, a video processor with or without a video recorder, and various video accessories. All of the chip cameras are fully immersible and shielded from electrical interference that may be created by cutting or coagulating currents during endoscopic procedures [7]. The CCD chip high-resolution camera should have an automatic white balance feature which allows one-touch color balance assuring true-to-life color reproduction. Additional features of the CCD camera may include a high-gain option which will boost the video signal to provide an exceptionally clear image, as well as a color bar option that allows the surgical team to adjust the monitors to represent accurate camera color prior to beginning the case.

Advances in CCD camera technology have significantly downsized current endoscopic video cameras, thereby allowing easier movement of the endoscope with the attached camera. With the recent significant improvements in CCD technology, tube cameras are no longer utilized due to their large size. When recording an actual endoscopic procedure, the camera may provide a remote control switch for a video recorder allowing instant fingertip pausing of the recording device during documentation. Additionally, the camera head should be designed to prevent fogging between the coupling device and the camera head. All manufacturers can supply camera-head adapters for other endoscopic systems. Finally, the entire camera head cable and edge card should be completely cold-soakable in disinfectant solutions for easy sterilization between endoscopic cases.

As noted, CCD chip cameras have supplanted tube cameras, which were the first video systems on the market. A significant improvement in CCD camera technology has been the development of the three-chip camera, which contains three individual CCD chips for the primary colors: red, green, and blue (Figure 3.1). In addition to composite SVHS and component signals, the three-chip cameras also provide an "uncoded" red, green, and blue signal. Color separation is achieved using a prism system overlying the chips [8]. This three-chip camera design provides improved color fidelity and enhanced image resolution. Moreover, three-chip cameras produce less "noise" due to the pure red-green-blue signals [9, 10]. A digital converter captures each voltage signal as an image and translates the voltage

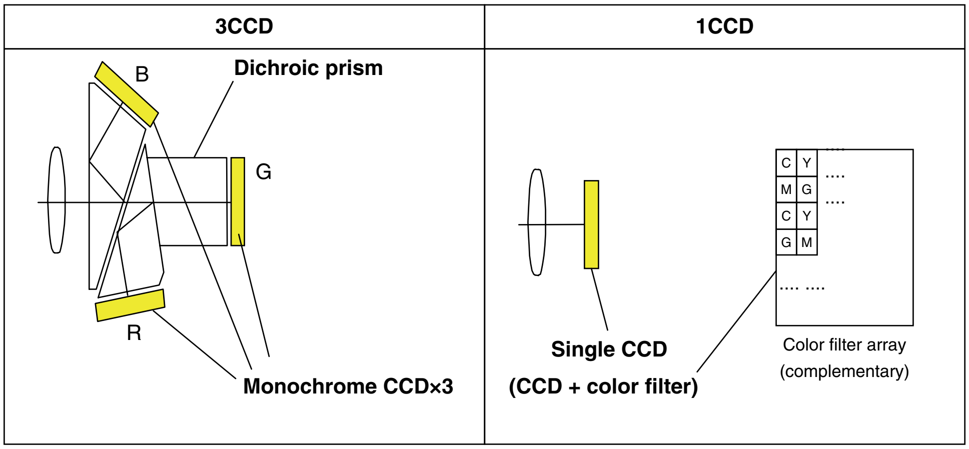

**Figure 3.1** Schematic representation of three-CCD-chip and one-CCD-chip designs. Red, green, and blue are sent to three separate CCDs by a prism. Reproduced with permission of Olympus.

values into discrete numbers, either as 0 or 1. The encoded numbers for each image element, or pixel, include information on color, light intensity, and contrast. These variables can then be modified using image-processing software within the camera [11].

Many CCD chip cameras (both single-chip and three-chip) contain electronic shuttering mechanisms that automatically adjust exposure time from 1/60 to 1/16 000 of a second (Figure 3.2). The advantage of such a sophisticated detection circuit is that the camera can react to varying light conditions almost instantaneously, reducing the flaring, "washout," and "blackout" which were noted with early video systems. Moreover, electronic shuttering mechanisms within the camera usually work more quickly than automatic light sources.

Some of the newer additions to three-chip camera technology are improved ergonomic designs (light weight and 90° rotation functionality) (Figure 3.3), wireless transmission capabilities when used with wireless monitor systems, and programmable buttons that allow high-definition (HD) image capture, video recording, image magnification, auto focus, and light source control by the operating urologist. Compatibility with the latest video-enhancing devices, such as Clarity (Stryker, Kalamazoo, MI, USA) and with modern imaging technology such as narrow band imaging (Olympus, Center Valley, PA, USA) and IMAGE 1S (Karl Storz, Tuttlingen, Germany) further improve visualization and facilitate video documentation.

## Videoendoscopes

A major advance in the endoscopic systems has been the development of the digital videoendoscope. Miniaturization

of chip technology now allows a CCD chip to be incorporated at the distal end of the endoscope (Figure 3.2). Instead of relaying optical images from the objective lens at the distal end of the scope to a camera attached to the eyepiece, the image is immediately captured by the CCD chip, digitized, and converted into electrical signals for transmission (chip-on-the-tip technology). This endoscope design has fewer interfaces allowing the digital information to be directly transmitted to an image display unit with minimal image loss, interference, or distortion [12, 13]. The creation of true videoendoscopes especially benefits the flexible ureteroscope and cystoscope. As internal optics are not required in the long and flexible shafts of these instruments, durable deflection mechanisms can be utilized to improve the durability of flexible endoscopes [14, 15]. With no need to attach a camera head to the eyepiece of the scope, the videoscope cable can be secured to the light cord for attachment to the video system, providing a more lightweight and convenient setup. This technology has been incorporated into larger, rigid endoscopes (laparoscopes), as well as rigid and flexible cystoscopes and ureteroscopes [16–18]. This innovation is due to recent technological advances which have now allowed miniaturization of CCD chips. One can expect to see such an integrated digital videoendoscope to replace many endourologic endoscopes in the near future.

Another development in digital camera technology includes the use of a single monochrome CCD chip with alternating red, green, and blue illumination to form a color image rather than using three chips with three separate color filters. This design reduces the space requirements and takes advantage of established high-resolution monochrome CCD chip technology [12].

Other techniques under development for image resolution enhancement include the use of complementary metal oxide semiconductor (CMOS) technology to replace the CCD sensors [19]. Both CMOS and CCD imagers are manufactured in a silicon foundry and the equipment used is similar. But alternative manufacturing processes and device architectures make the imagers quite different in both capability and performance. It is technically feasible but not economical to use a CCD processor to integrate other camera functions, like the clock driver and signal processing. These are normally implemented into secondary chips. Thus, most CCD cameras comprise several chips. On the other hand, one of the major benefits of CMOS cameras over the CCD design lies in the high level of product integration that can be achieved through virtually all of the electronic camera functions onto the same chips. Typically, a CMOS processor allows lower power usage and lower system cost. This technology is currently being used for digital ureteroscopy [20].

Several *in vivo* and *in vitro* studies have compared the new digital flexible cystoscopes to fiber-optic flexible cystoscopes in terms of their optical characteristics [21–24]. The compared optical characteristics included image resolution, grayscale imaging, color representation, color differentiation, depth of field, image brightness, and the urologist's subjective assessment of image quality. The digital flexible cystoscopes were superior to fiber-optic flexible cystoscopes in almost all optical parameters.

In addition to the improved imaging quality of the white light digital cystoscopes, the use of optical and video enhancing techniques, such as fluorescence cystoscopy/photodynamic diagnosis (PDD), narrow band imaging (NBI), confocal laser endomicroscopy (CLE), and optical coherence tomography (OCT) have extended the quality of information that these cystoscopes can deliver [25].

The PDD modality, or hexaminolevulinate-guided blue-light cystoscopy, uses photosensitive protoporphyrin analogues as intravesical contrast agents combined with a blue-light-source (375–440 nm) cystoscope to stimulate fluorescence. Selective accumulation of the photosensitizers by cancer cells causes tissue to appear distinctively red when visualized with blue light cystoscopy (Figure 3.4). There is evidence that the use of this modality improves detection, and consequently treatment, of non-muscle invasive bladder cancer. A newer body of evidence suggests that blue-light cystoscopy helps decrease recurrence, and even progression, rates of non-muscle invasive bladder cancer through better visualization and diagnosis and it has proven to be cost effective [26–29].

The NBI technique (Olympus) is based on a light source that filters white light into two narrow wavelengths (415 and 540 nm) that are strongly absorbed by hemoglobin, enhancing the contrast between capillaries and mucosa without the use of dye. Enhanced contrast helps differentiate the more vascularized malignant areas from normal and benign urothelium. The Olympus High Definition Flexible Cysto-Nephro Videoscope (HD CYF-VH; Olympus) is equipped with this functionality. In addition to its HD quality images, this cystonephro videoscope has a wide 120° field of view, improved deflection (220° up, 130° down), 150% increased light output, and 20% brighter NBI when compared to the previous model, CYF-V2. When compared to white light cystoscopes, NBI-supported flexible cystoscopes have been shown to improve urothelial cancer detection in multiple studies [30–34].

Based on a similar technology, Karl Storz (Tuttlingen, Germany) has recently introduced the Storz Professional Image Enhancement System (SPIES) that is used with their IMAGE 1 S camera unit. Homogenous illumination, color enhancement, and shifting the color spectrum of the image obtained by the digital flexible ureteroscope, Flex-Xc, offers clearer tissue differentiation through three different viewing options (CLARA, CHROMA, and SPECTRA) that can be displayed side by side with the traditional white light digital image. The SPIES technology is currently at early stages of clinical investigation [35–37].

CLE and OCT are two of the newer imaging modalities. These microscopic modalities are based on fiber-optic probes used with standard cystoscopes that enable high-resolution subsurface characterization of suspected lesions, providing information on tissue microarchitecture and cellular morphology that is not possible with traditional white light, PPD, or NBI imaging technologies. The clinical validity and applicability of these technologies are still under investigation [23, 33, 38, 39].

Similar advanced optical technologies have been incorporated into the newer digital ureteroscopes. Use of the CCD and CMOS chip-on-the-tip digital technology has allowed high-definition visualization, autofocus capabilities, and digital magnification with decreased diameter of the ureteroscope shaft (Figure 3.2). Several studies have compared the currently available digital ureteroscopes with their previous generations and fiber-optic counterparts in terms of resolution, contrast, depth of field, color representation, illumination, and mechanical properties. The digital ureteroscopes have been shown to have superior visualization and imaging quality compared to the fiber-optic scopes in all of these studies [40–49].

The available modern flexible digital ureteroscopes are the Flex-Xc (Karl Storz), the URF-V2 (Olympus), and the BOA Vision (Richard Wolf, Knittlingen, Germany) (Figures 3.5–3.7). All of these flexible ureteroscopes have one or two integrated light emitting diodes (LED) light source, are capable of auto-focus and automatic adjustment of light intensity, offer wide (90°) field of view, have a 3.6 Fr working channel and can deflect 270° in both directions.

The Richard Wolf's BOA Vision and the Karl Storz's Flex-Xc ureteroscopes use CMOS, while the Olympus URF-V2 ureteroscope uses a micromini CCD, chip-on-the-tip technology. This technology eliminates the need for fibers to transmit images, which allows for decreased diameter of the scope (8.9, 8.5, and 8.4 Fr for the BOA Vision, Flex-Xc, and URF-V2 ureteroscopes, respectively).

The Olympus URF-V2 flexible ureteroscope is equipped with NBI technology that uses different light wavelengths to enhance tissue contrast, as discussed. The role of NBI technology is well established in urothelial carcinoma of the bladder. Although its role in upper tract urothelial carcinoma is theoretically promising, it is still in the early stages of investigation [50].

The Karl Storz Flex-Xc flexible ureteroscope is equipped with the Karl Storz SPIES technology that changes color enhancement and shifts the color spectrum to produce different image modalities with unique tissue enhancements. The clinical applicability and presumed advantage in detecting upper tract urothelial carcinoma using this technology has not been investigated yet. In addition to SPIES technology, the Flex-Xc flexible ureteroscope has PDD capability that uses

photosensitizers (5-aminolevulinic acid) to enhance urothelial malignant tissue fluorescence [40]. The use of this technique has been described in few reports and thus its clinical application is still under investigation [37, 51–53].

A newer addition to the flexible digital ureteorscope family is the LithoVue System (Boston Scientific, Marlborough, MA, USA), which is a single-use digital flexible ureteroscope. This ureteorscope uses CMOS chip-on-the-tip technology. Its light source is built into the handle, which is wired to a touch-screen monitor that is mounted on a mobile cart for portability (Figure 3.8). The ureteroscope has an outer diameter of 9.5 Fr and a single 3.6 Fr working channel. It can deflect 270° in both directions. Although the visibility and maneuverability of this ureteroscope has been shown to be comparable to those of a fiber-optic flexible (URF-P5; Olympus) and a digital ureteroscope (URF-V; Olympus) in one small study [54], its incorporation into daily clinical practice and cost effectiveness is yet to be explored.

Laparoscopy has witnessed similar, if not further, advancements in optical technology. HD digital laparoscopes are currently available for use and offer many significant advantages over standard-definition (SD) laparoscopes. Surgeons have subjectively rated HD images superior to SD images during laparoscopy in both the laboratory and clinical settings [55]. One recent study performed an objective comparison of performance characteristics between the Olympus HD 10 mm laparoscope (Olympus) and the Olympus SD 10 mm zero-degree laparoscope [56]. The HD laparoscope had improved resolution, decreased distortion, greater depth of field, and improved luminous flux when compared to the SD laparoscope. Given the importance of visual cues

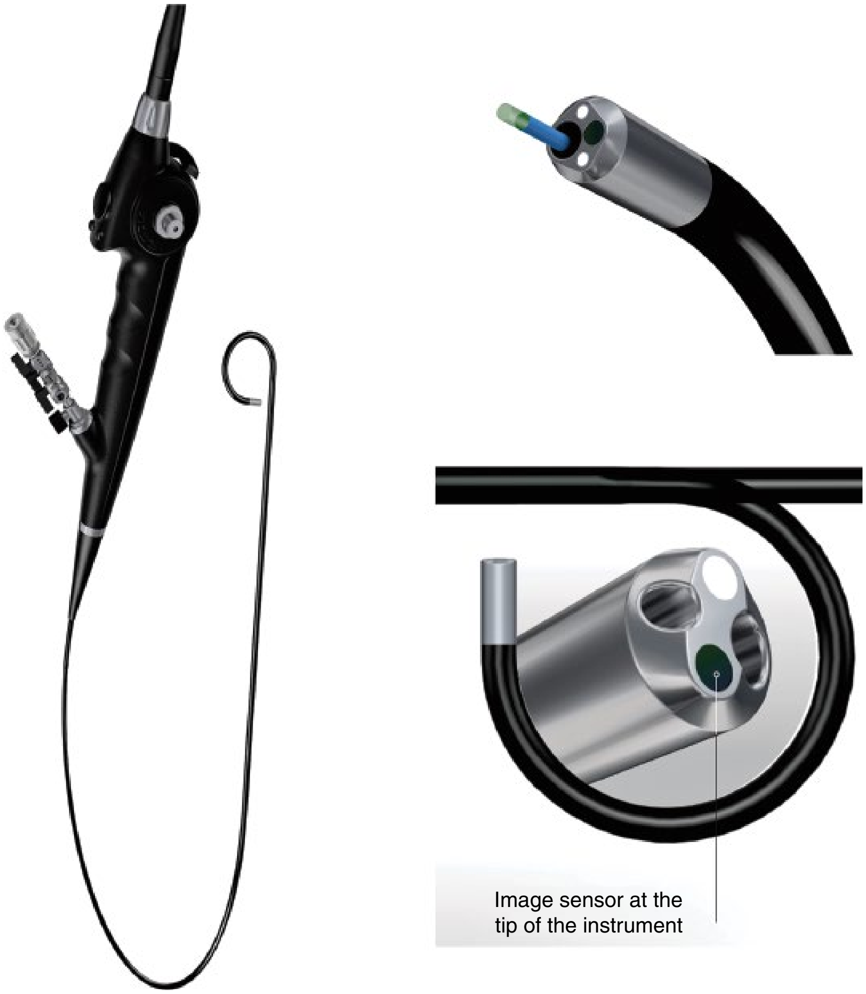

**Figure 3.7** The Richard Wolf digital flexible ureteroscope BOA Vision with chip-on-the-tip technology and dual LED light source. It is also equipped with Wolf's image sensor technology at the tip. Reproduced with permission of Richard Wolf GmbH, Knittlingen, Germany.

in performing laparoscopic surgery, these improvements could be of great significance. Laparoscopy performed with an HD camera in combination with HD monitor can improve the performance of surgical tasks, specifically laparoscopic knot tying, which requires precise depth perception [55, 57].

The newer telescopes offer HD and ultra-HD (UHD) images in wide angles. Olympus has introduced an articulating flexible tip HD videoscope (ENDOEYE FLEX LTF-S190-5; Figure 3.9) that, in many ways, resembles an ureteroscope. It also uses chip-on-the-tip technology and has built-in NBI technology. The articulating tip can bend in all directions up to 100°, which offers flexibility during surgical procedures and eliminates the need to constantly switch telescopes (for example from 0° to 30° and vice versa). It has a focus-free optical design that provides greater depth of field and eliminated the need for manual focusing. Similar to a digital ureteroscope, it has an integrated single light and camera cable that connects to the camera and the light source systems.

Another modern telescope is the EndoCAMeleon® from Karl Storz. This telescope does not have a flexible tip but it has a mobile lens with an adjustable direction of vision (0–120°). The operating surgeon can control the direction of view from the scope handle. It thus eliminates the need to switch scopes of varying angles (for example from 0 to 30° and vice versa) during surgical procedures (Figure 3.9).

The latest advancement in laparoscopic imaging technology is the introduction of the UHD 4K imaging resolution system. 4K resolution refers to a display device or content having horizontal resolution in the order of 4000 pixels and vertical resolution in the order of 2000 pixels. It offers four times the resolution of full HD and much more detailed images. This technology is introduced by the Visera 4K UHD system (Olympus). Visera 4K UHD supports both 4K UHD (3840 × 2160) and full 4K (4096 × 2160) resolution. This system generates a wider color gamut by adopting the 4K color format (BT2020) and display in a panoramic view. It allows surgeons to observe fine patterns and structures in high precision and recognize much more subtle differences in

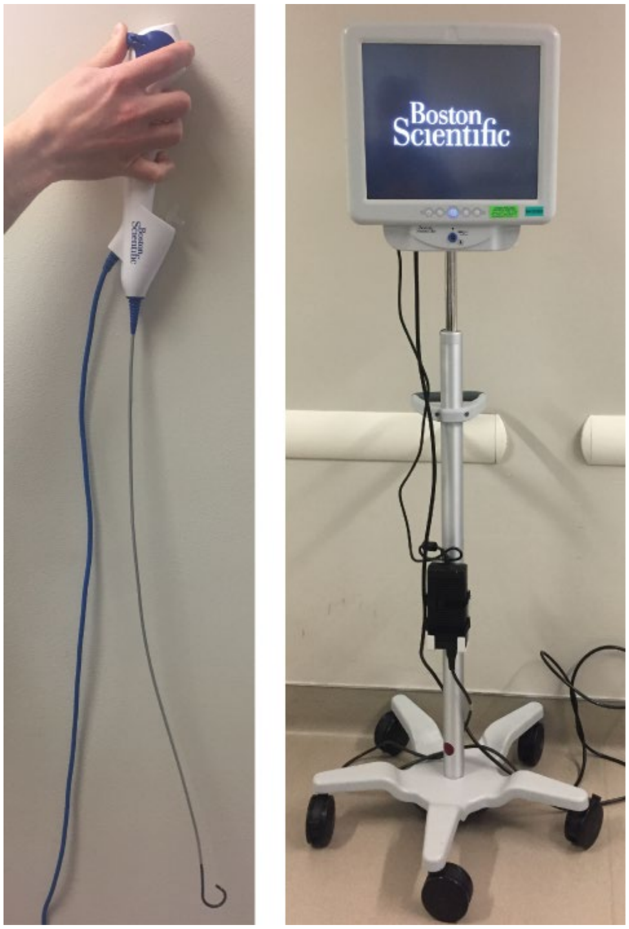

**Figure 3.8** The Boston Scientific single-use digital flexible ureteroscope LithoVue with chip-on-the-tip technology. Note the portable display cart that connects to the ureteroscope. Reproduced with permission of Olympus.

reds and yellows than conventional HD. It also has electric magnification capability that is equivalent to full HD resolution even at 2.0× zoom.

The abovementioned advancements in laparoscopic imaging technology have certainly improved the surgeon's experience in the operating room. The impact on clinical outcome has not been investigated yet.

## Video light sources

In addition to a CCD camera, a high-intensity light source, usually halogen, xenon, or light-emitting diodes (LED), should be utilized for appropriate illumination. Certain light sources have an automatic light sensing feature which quickly adjusts the light output as required by the camera. This automatic light adjustment feature is particularly helpful during endoscopic procedures, as the endoscope may be rapidly moved throughout the abdominal cavity or urinary tract, causing areas of too much or too little illumination. Light intensity will be automatically altered to maintain a pre-selected illumination level. As noted previously, some camera systems are equipped with an "automatic iris" system which will electronically increase or decrease the "aperture" of the camera shutter (Figure 3.4). If the camera system is equipped with such a light-sensing feature, there is no need for an automatic light-adjusting light source. Newer CCD or image sensor-based endoscopic cameras feature electronic exposure. This system varies the effective exposure period (i.e. light-gathering time) of the CCD as the live image is captured. Typical CCD exposure periods range from approximately 1/60 of a second to 1/10 000 of a second under very bright conditions. This electronic process can be used to maintain the brightness in the image. When the image brightness must be reduced to improve picture clarity, the image signal exposure period can be reduced electronically instead of adjusting the iris of the light source.

Shadows play an important role in depth perception and spatial orientation. Studies have demonstrated that endoscopic task performance significantly improves with video systems that provide proper illumination and appropriate shadows in the operative field [58]. Many of the current endoscopes employ a simple frontal illumination technique that produces an optically flat and shadow-less image with resultant poor contrast. Newer illumination and imaging technologies provide shadow-inducing systems using a single-point or multipoint illumination system. One of these techniques employs the use of two independent illumination fiber bundles, with one fiber bundle ending at the front lens, as designed in conventional endoscopes and the other fiber bundle ending behind the tip of endoscope. This configuration results in an improved image with better contrast due to shadow formation. Spatial orientation and perception between anatomical structures are considerably enhanced [19].

The newer endoscopic light sources generate light using LED technology. Compared to xenon lamps, LED lamps are more economic, more efficient, produce a similar light intensity that is consistent throughout the life span of the bulb, and are quieter than xenon lamps. Moreover, some manufacturers have improved on LED technology by using laser-integrated LED systems. One such example of LED Laser hybrid system is the POWER LED 300 (Karl Storz). It is claimed that this technology can deliver up to twice the light intensity of conventional LED light sources to the operative field.

Portability has recently become one of the desired features in light source technology. Recently, Cook Medical (Bloomington, IN, USA) have introduced a rechargeable, portable LED light source (VueLite® LED Light Source). This device is lightweight (approx. 85 g), small (90 mm in length), and powered by a rechargeable lithium-ion

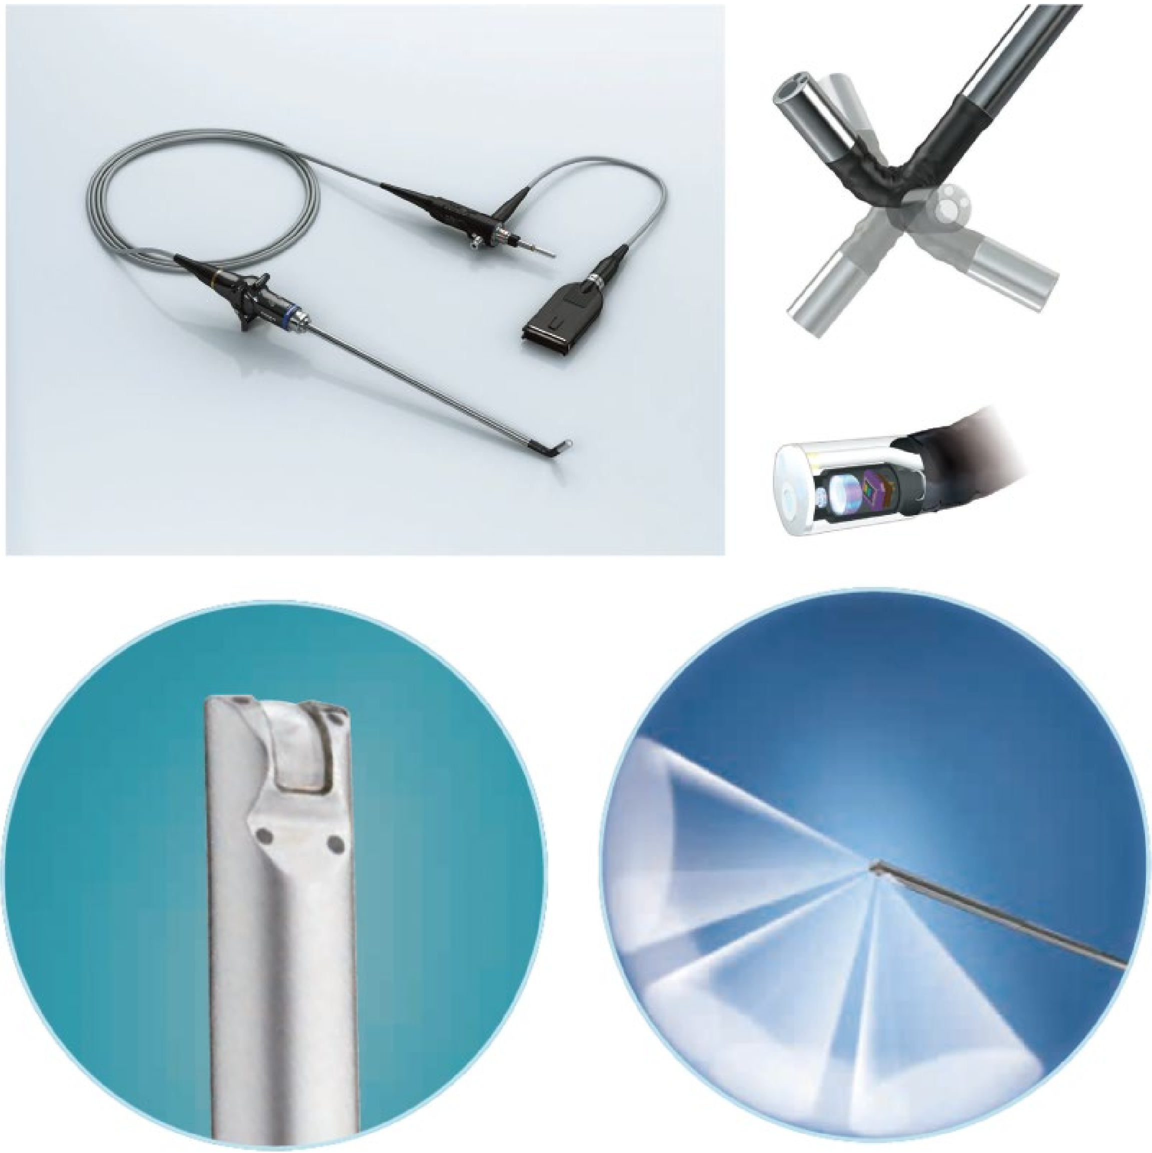

**Figure 3.9** Advances in laparoscopy. Top: ENDOEYE FLEX 2D-3D digital laparoscope with 100° articulating tip and multi-CCD chip technology (Olympus). Bottom: EndoCAMeleon telescope lens that can be adjusted in five steps from 15 to 90°. Reproduced with permission of Karl Storz GmbH.

(Li-ion) battery. It has an adjustable light intensity that, on a full 2 hour charge, can provide up to 2 hours of light for endoscopic procedures. The lifetime of the LED is around 1 million hours [59].

## Video system setup

### Video cart

An essential part of any video system should be the video cart. This cart is an integral component for the entire system, which allows one to easily transport the video documentation system from one surgical suite to another. The video cart should have room to hold the video camera electronics, the light source, and various recording devices such as a hard copy printer or digital recorder (Figure 3.10). Moreover, some video carts will also have room to hold the laparoscopic insufflator as well as electrocautery units. One should be able to adequately secure the cart during storage to prevent equipment loss. Finally, ensure that the video cart has the capability to hold $CO_2$ tanks which will be needed during laparoscopic procedures.

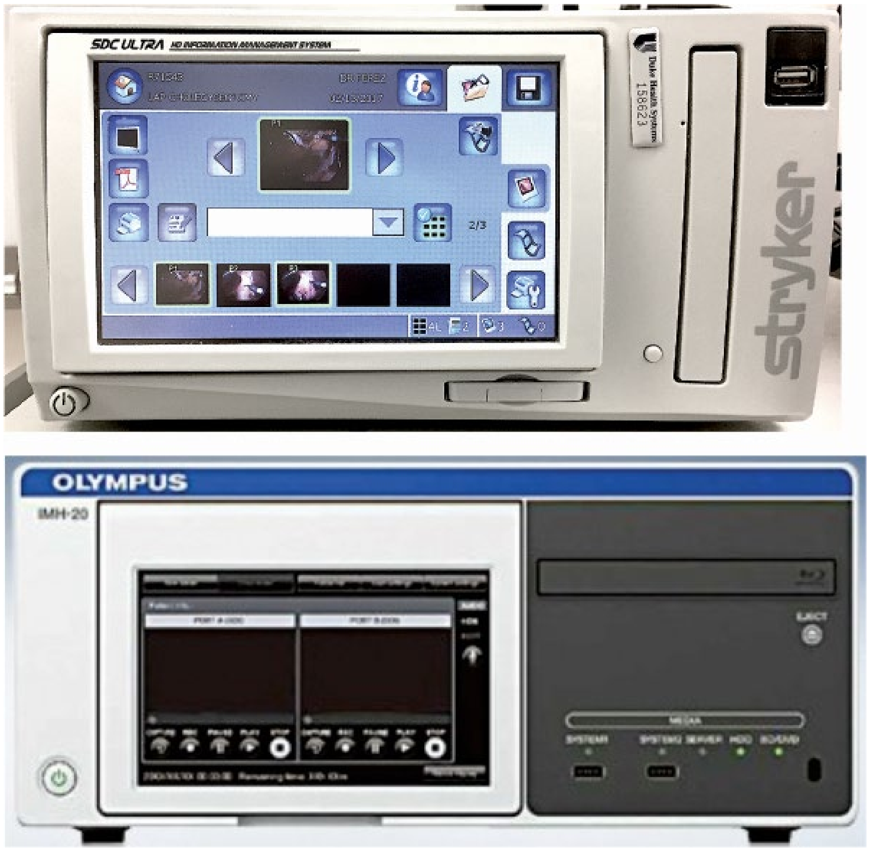

**Figure 3.10** Touch-screen, image processing, and documentation systems. They offer direct capture of high-quality still images and surgical videos on a variety of digital storage media (USB storage drives, internal hard drives, and DVD or Blu-ray discs). Top: SDC Ultra (Stryker). Bottom: IMH-20. Reproduced with permission of Olympus.

### Video setup

Traditionally, our standard operating room setup places the video cart, which contains a video camera and recorder, television monitor, and xenon light source, directly across from the operating surgeon. In addition, a second high-resolution video monitor will be placed on the other side of the table to be used by the assistants. If only one video monitor is available, it should be placed directly at the end of the operating table. All endoscopic procedures in our endoscopy suite and operating rooms are performed entirely off the video monitor(s).

With the advent of newer operating room designs, the fundamental differences between open and endoscopic or laparoscopic surgery have been recognized. Whereas in the past endoscopists and laparoscopists relied upon mobile carts traveling from room to room, today specialized rooms provide dedicated carbon dioxide lines, preventing the need to change tanks in mid-operation. Another issue relating to suboptimal operating room design is the effect of imperfect ergonomics on surgeon comfort from a musculoskeletal standpoint. Many recent studies have demonstrated significant stressors to the surgeon induced by laparoscopy. Many of these stressors are related to monitor placement, camera holding, trocar placement, and table position and height [60–63]. Operating room enhancements, such as ceiling mounted monitors and designs focused on the endoscopic and laparoscopic surgeons, allow for versatility in the ergonomics surrounding minimally invasive urologic procedures (Figures 3.11 and 3.12). Whether or not these specially designed operating rooms reduce musculoskeletal complications in surgeons has yet to be determined, but some studies indicate that this is in fact the case and that overall operating room efficiency is improved as well [64, 65]. A novel addition to the operating room of the future may incorporate high-resolution binocular face-mounted devices such as has been explored at the bench level, thus providing less surgeon neck/back strain and improved visualization and satisfaction compared to conventional standard video monitors [66].

## Future directions of endoscopic video systems

3D video systems as well as HD have been introduced to significantly improve visualization during minimally invasive surgical procedures. In addition, augmented reality techniques have been developed, which allow enhanced image processing of videoendoscopic procedures as well

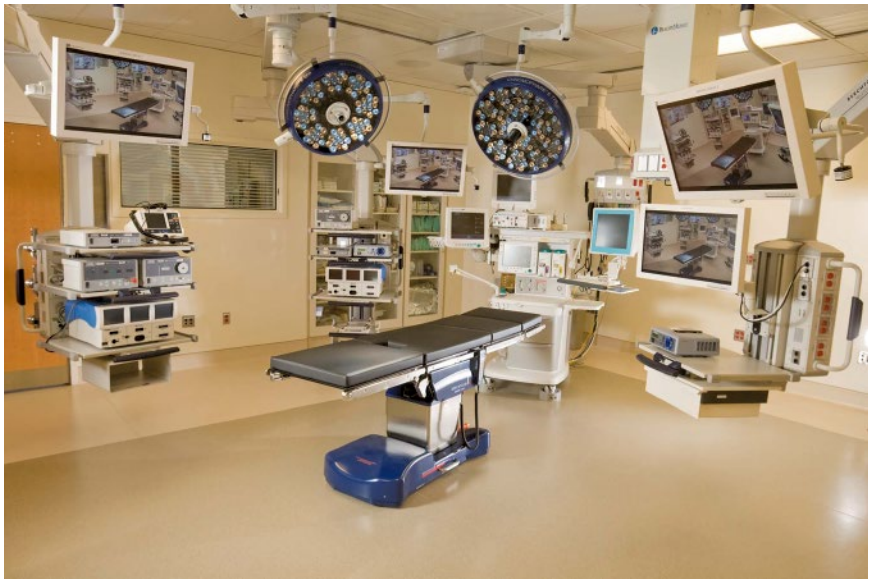

**Figure 3.11** Current operating room with HDTV monitors.

as the development of surgical simulations to aid in training of complex surgical maneuvers. The following sections will review these enhanced imaging technologies for endoscopic surgery.

## 3D video imaging

3D video imaging enhances the ability to perform delicate endoscopic maneuvers, such as dissection or precise suturing [67]. Moreover, those who are observing have a better understanding of the surgical anatomy because of the 3D image.

### Principles of 3D stereoendoscopy

In normal human vision, depth perception is a factor taken for granted. Normally, the eyes will accommodate and converge in such a way that there is intersection of the visual axes of both eyes. This intersection is known as the point of fixation. When viewed by both eyes, lateral disparity causes the viewed object to be projected in slightly different orientations on the retina of the right and left eyes. The human brain interprets this disparity on a small region of the retinal fovea (called Panum's region) as depth information. The brain then fuses these images to give the perception of depth, and this effect is called stereopsis [68].

Accommodation is the ability of the human eyes to clearly visualize objects which are both near and farther away. The eyes converge, and the lens increases its dioptic strength so that the object is brought into sharp focus on the retina. The nearest an object can be to the eye and still be in focus is called the near point, while the farthest it can still be in focus is called the far point. The region of depth is the area between the near and far points. This ability to accommodate is preserved when viewing objects with a 3D video system.

To mimic normal 3D vision, a 3D video system must therefore convey separate off-set images to each eye. The figure is captured in a slightly different orientation by the stereoendoscope and after image processing by the brain, it appears as a 3D object. Any 3D video system must therefore incorporate the principles of stereopsis [68, 69]. One potential limiting factor of 3D endoscopic systems is that the normal interpupillary distance for human vision is approximately 60 mm, while the maximum separation of two objective lenses in a standard 10 mm endoscope is approximately 8 mm. Various endoscopic designs, however, have accounted for this disparity, still allowing for adequate capture and display of 3D images.

### Stereoendoscopic image processing

Most of the 3D stereoendoscopic video systems currently available have four basic principles of stereoendoscopic image processing in common: image capture, conversion of 60 Hz to 120 Hz images, presentation of left and right images on a single monitor, and separation of the left- and right-eye images [70]. While the components of the various 3D video systems may differ slightly, they each contain the same basic principles.

### 3D display

The 3D conversion system will sequentially display the left- and right-eye images on the 120 Hz 3D video monitor. However, in order to view the left- and right-eye images on a single monitor, the images must be separated. One method involves "active" liquid crystal display (LCD) shutter glasses. These glasses are synchronized by an infrared emitter which is located on top of the video monitor. As the left-eye image is projected on the video screen, the emitter will control the shutter glasses so that

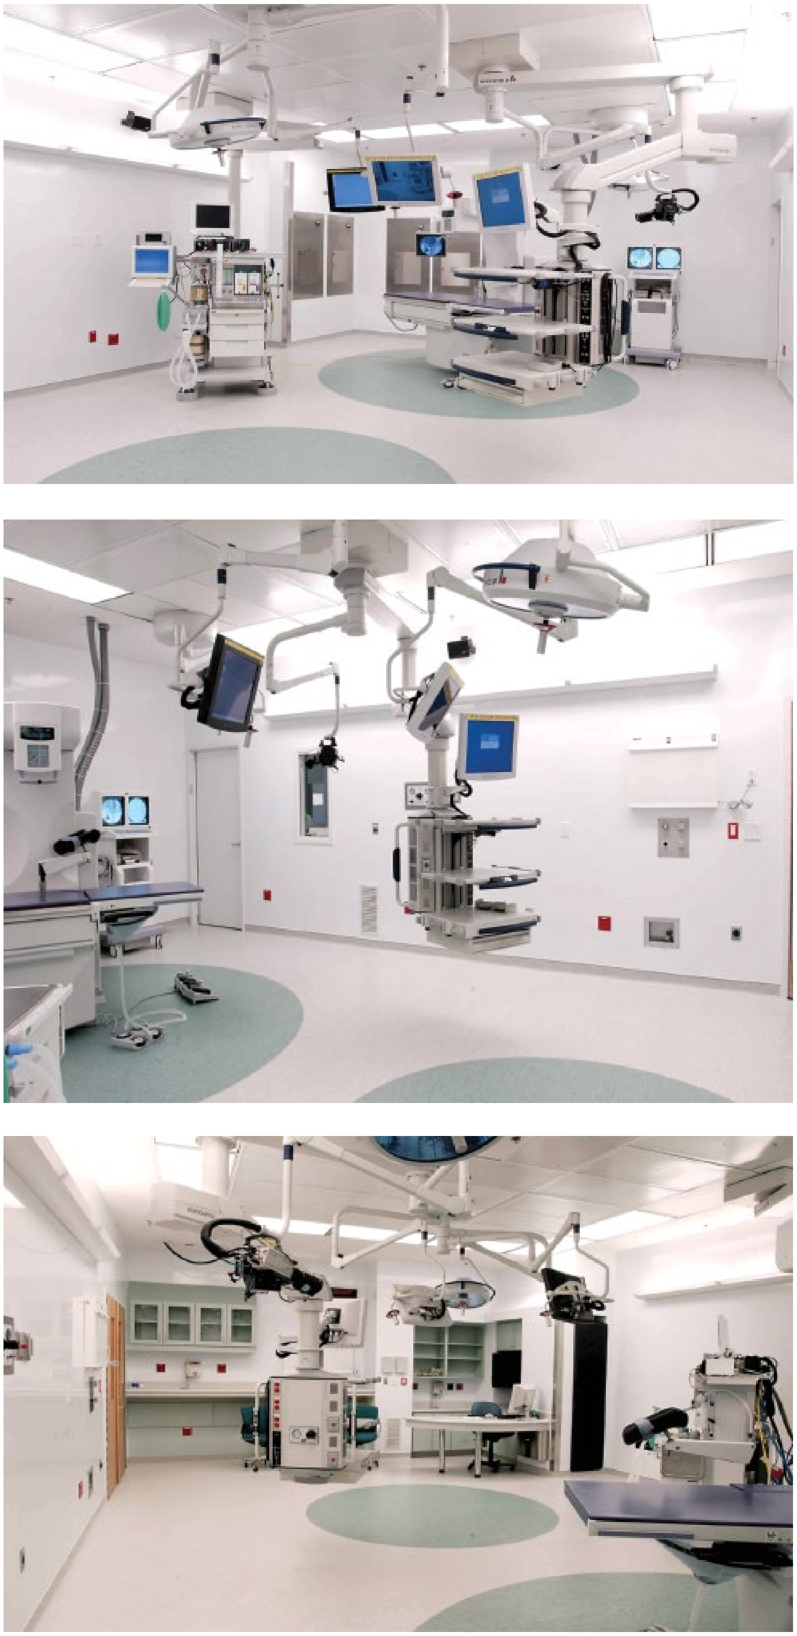

**Figure 3.12** Current operating room with HDTV monitors.

the right eye is closed and left eye open. Alternatively, when the right eye is open, the left side of the LCD glasses is blackened and the right eye image appears on the video screen. The advantage of this active system is that more light is projected to each eye and therefore the 3D image appears brighter. However, the active LCD shutter glasses require a battery, are somewhat heavy, and quite expensive.

Alternatively, "passive" polarized glasses may be worn to view the left- and right-eye images from the single video monitor [71]. This type of system requires a special polarizing filter on the video screen which will "rotate" the left- and right-eye images in different orientations thereby allowing simultaneous viewing of the left and right images. The passive polarized glasses have the advantage of significantly cheaper cost than the active LCD shutter glasses and are more comfortable to wear, but the polarizing glasses present a slightly darker 3D image than the active glasses.

An alternative to dual projection is the presentation of the two images independently to the left and right eye, much like looking through field binoculars. The images can be displayed on small screens set at the focal distance for the surgeon and mounted on an ergonomic headset [72]. This technology is currently available as part of the da Vinci robotic system [73].

#### Advantages of 3D videoendoscopy

The increased depth of field afforded by 3D endoscopic video systems facilitates intricate minimally invasive surgical procedures [74, 75]. Addition of a third dimension allows better recognition of tissue layers and may facilitate complex maneuvers such as laparoscopic suturing or knot tying [57, 76]. Indeed, skill tests performed assessing laparoscopic suturing and knot tying have demonstrated a 25% increase in speed and accuracy of these laparoscopic tasks when utilizing a 3D video system as compared to a standard two-dimensional (2D) endoscopic video system [77]. Some investigations claim that 3D video systems only facilitate surgical tasks in inexperienced laparoscopic surgeons. It appears that the reduction in time required to perform various minimally invasive surgical procedures may not be as dramatic in those individuals who have a large amount of experience with standard 2D video systems during endoscopic surgery [72]. Some studies suggest that a higher-resolution video system might be more advantageous than having 3D endoscopic imaging [78–80]. The major current use of 3D imaging systems is during robotic, more than laparoscopic, surgical procedures to allow for true stereoscopic imaging [81–83].

#### Limitations of 3D imaging systems

Late-model 3D videoendoscopic systems compared with initial 3D components provide greatly improved 3D viewing of minimally invasive surgical procedures. Yet, they still provide reduced resolution and lower-light images as compared to standard single-chip or three-chip 2D video camers. The decrease in image brightness and resolution is due to the fact that most 3D video systems use two optical channels which are significantly smaller than a single-lens system in a standard 10 mm laparoscope. Moreover, since most 3D video systems incorporate two separate camera systems, the camera head is significantly larger than a single-camera system and, therefore, more cumbersome to work with during minimally invasive surgical procedures.

Cost continues to be a limitation of 3D videoendoscopy. Most 3D video systems are two to three times more expensive than standard 2D endoscopic video cameras. While 3D video imaging systems are more costly than conventional 2D video equipment, the enhanced depth perception produced by 3D endoscopes has been demonstrated to improve the performance of minimally invasive surgical procedures [84, 85]. 3D imaging also facilitates the training of minimally invasive surgery and may lessen the learning curve of these technically demanding procedures [86]. It is anticipated that 3D video imaging may improve the performance of current endoscopic procedures as well as facilitate the development of more advanced, minimally invasive surgical techniques [67].

### Image-guided surgery

Image-guided surgery (IGS), computer-assisted surgery (CAS), or augmented reality (AR) involve the integration of preoperative radiologic imaging with real-time intraoperative surgical views (Figure 3.13). It allows the surgeon to "see" subsurface information which is inaccessible through ordinary endoscopic imaging. Augmented reality and imaged guided surgery have many potential advantages to conventional endoscopic surgery. AR has the potential to replace the loss of haptic feedback in robotic and laparoscopic surgery by allowing surgeons to see anatomic and spatial relationships that are not obviously apparent through standard or 3D views. In addition, AR and IGS have the potential to predict surgical results beforehand [87]. These features have the potential to minimize the loss of healthy tissue while maximizing oncological efficacy.

Various techniques have been described for the implementation of IGS and AR. Real-time virtual sonography (RVS) has been described, allowing synchronization of preoperative computed tomography (CT) or magnetic resonance imaging (MRI) images with intraoperative real-time ultrasound images [88, 89]. The system displays the real-time ultrasound image and the corresponding image of a 3D reconstructed CT or MRI. This technology is especially useful for percutaneous ablative procedures for the kidney or prostate.

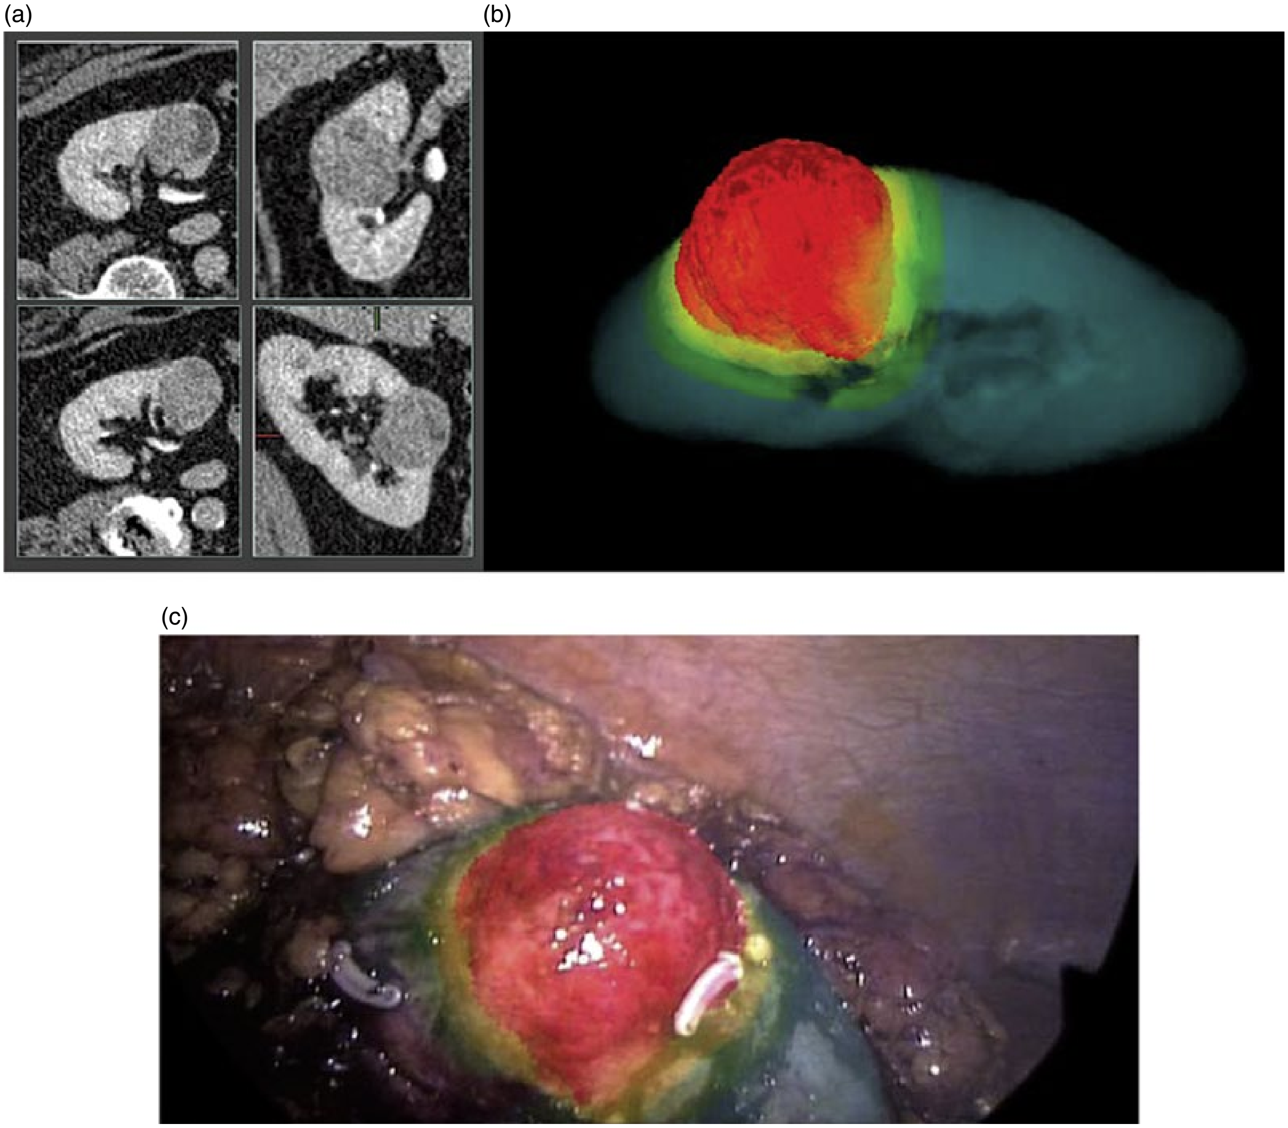

**Figure 3.13** Example of augmented reality navigation during laparoscopic partial nephrectomy. (a) Original CT images. (b) Four-color coded surgical model. (c) Augmented-reality image is superimposed onto the real-time surgical view. Reproduced with permission of Elsevier.

Other investigators have reported on the use of AR for laparoscopic partial nephrectomy [89]. They utilized an optical tracking system for their surgical instruments combined with a computer workstation to overlay preoperative 3D reconstructed images onto their surgical view. For laparoscopic partial nephrectomies, the images were displayed with colored zones corresponding with the tumor and various margins. Other techniques have been described for coordinating the preoperative images to the intraoperative view. One system placed navigation in the target organ for better localization and to account for organ movement [90]. This technique has been coined as the “inside-out tracking system.” The tracking system was able to overlay images onto the operative field with a 0.5 mm error margin.

Recently, Rassweiler et al. reported the use of marker-based navigation technique to obtain percutaneous access to the kidney for urinary stone treatments [91]. They used an iPad (Apple Inc., Cupertino, CA, USA) as a wireless video output source and, simultaneously, as the computer and display device to show enhanced virtual reality of the patient’s anatomy. Although interesting, the application of this technique in clinical practice has not been widely adopted yet.

AR has also been applied to robotic-assisted laparoscopic partial nephrectomy [92]. The system allows overlay of 3D models constructed from preoperative CT scans onto the 3D intraoperative video recordings. The advantage of this system is it did not require external tracking devices. Another model for AR utilized the da Vinci robot system as a single localizer [93]. This system demonstrated decreased removal of benign tissue in an *in vitro* model.

All of these systems currently allow for 3D reconstructed, preoperative images to be displayed onto real-time endoscopic surgical views. The major limitation is accounting for organ motion and deformity. The future of AR and IGS is predictive surgical navigation. Ukimura and Gill described surgical radar and surgical body-GPS [88]. Surgical radar involves displaying color-coded zones over the real-time image of an intended surgical target. The trajectory of an instrument, endoscopic scissors for example, can be used to predict whether the current path of that instrument will violate an undesirable structure, such as a tumor. Surgical body-GPS allows for monitoring of real-time organ position. The surgeon can be alerted to how real-time movement of the organ alters the line of excision for an intended target. The aim of this technology is to maximize normal tissue preservation and oncological efficacy.

## Conclusions

The application of video technology to endoscopic procedures provides several advantages in both the teaching and private practice settings not previously available to the urologist. Improved magnification and image quality facilitates performance of the procedure by the surgeon, as well as coordination of the assistants and ancillary personnel to provide a smoother, safer, and potentially shorter operation. Video monitoring facilitates teaching both during and after the procedure, as well as provides preoperative patient education. Moreover, videoendoscopic procedures also increase the safety of the procedure for the operating urologist.

As newer technologies, such as HDTV and 3D videoendoscopy, become more widespread, an increasing number of videoendoscopic procedures will be performed. The dissemination of the surgical skills needed to perform these surgical procedures is becoming increasingly important. Technologies such as augmented reality simulation and telementoring may become commonplace in the near future for the training of future urologists. These technologies allow for more rapid acquisition of skills necessary to perform complex endourological and laparoscopic procedures in a safe environment with reduced risks of adverse events for patients. Future technologies such as image-guided or computer-assisted surgery should only further improve the safety and efficacy of videoendoscopic procedures. With the advent of new technology for video imaging and documentation patient care provided by the endourologist and minimally invasive surgeon should rapidly improve.

## 4

# Preoperative Antibiotics and Prevention of Sepsis in Urologic Endoscopic Surgery

*Manish N. Patel & Jorge Gutierrez-Aceves*

*Wake Forest University School of Medicine, Department of Urology, Winston-Salem, NC, USA*

## Introduction

Sepsis from a urinary source is one of the most feared complications in urologic practice due to its potential for increased morbidity and mortality after urologic surgery. In this chapter, we will discuss the importance of appropriate preoperative workup, use of adequate antibiotic prophylaxis, as well as intraoperative and postoperative measures to help prevent the development of adverse events related to infection and sepsis.

According to the European Section for Infection in Urology, the prevalence of hospital-acquired infections varies between 3.5 and 9%. The prevalence of hospital-acquired urinary tract infections (HAUTI) was found to be 9.4% over an 8-year period between 2003 and 2010. The most common presentation was asymptomatic bacteriuria in 27%, followed by cystitis in 26%, and pyelonephritis in 20%. Some 10.3% of all cases presented as urosepsis [1]. Among those patients with nosocomial urinary tract infections (UTIs), almost 80% had a prior history of urologic surgery; endourologic procedures had been undergone in 50%, open or laparoscopic surgery in 45%, and prostate biopsies in 5% [2]. These data suggest that preventive measures, such as a strict preoperative evaluation and correct antibiotic prophylaxis in surgical patients, must be improved.

The prophylactic use of antibiotics can reduce the risk of surgically related infection. The European Association of Urology (EAU) and American Urological Association (AUA) have both published guidelines for best practice in antibiotic prophylaxis in urologic surgery. The AUA most recently updated their guidelines in 2009 and the EAU in 2014 [3, 4]. These guidelines are extremely helpful to standardize the administration of antibiotics prior to surgery. However, local practice should be based on or adjusted according to local or even hospital microbiologic patterns and requirements, so it is crucial that each center and department reviews regularly its infection patterns and antibiotic resistance.

There is currently no uniformly accepted definition in the literature to delineate infection versus sepsis, which may account for the wide range of incidences reported [5]. After any diagnostic or therapeutic urologic procedure, UTIs can be present as a simple bacteriuria with limited clinical symptoms or they can result in severe sepsis or even septic shock. It is difficult to predict in which patient a serious complication will develop, but several publications describe potential risk factors that can contribute to this scenario. It is crucial to recognize patients at risk of complications with a complete preoperative evaluation to establish a prompt diagnosis and proper treatment in the event of a postoperative infectious complication.

## Pathogenesis of urosepsis

Classically, urosepsis is defined as a sepsis caused by UTI; this occurs in 7–25% of all septic cases [6]. An infectious complication is triggered during urologic surgery when urinary bacteria and their products enter the bloodstream via a vascular, lymphatic, or urothelial disruption. Manipulation of infected urine or infection stones with an increase in pressure mainly in the collecting system causes an intense liberation of bacteria and endotoxins via direct absorption, pyelovenous–lymphatic or pyelotubular backflow, and forniceal rupture, triggering a systemic inflammatory response [7].

There is a neurohumoral generalized pro- and anti-inflammatory response. This begins with cellular activation of monocytes, macrophages, and neutrophils that interact with endothelial cells through numerous

© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

pathogen-recognition receptors [8]. A further host response includes the mobilization of plasma substances, such as tumor necrosis factor (TNF), interleukins (ILs), caspases, proteases, leukotrienes, kinins, reactive oxygen species, nitric oxide, arachidonic acid, platelet activating factor, and eicosanoids. TNF-α and IL-1 are the most important proinflammatory cytokines and exhibit similar biologic properties. They influence the temperature regulatory centers in the hypothalamus, resulting in fever. They also have an effect on the formation reticularis in the brainstem, which renders the patient somnolent and comatose. Release of corticotropin in the pituitary gland is increased, which stimulates the adrenal gland. These factors also stimulate hematopoietic growth factors, which leads to the formation of new neutrophils and the release of stored ones. The neutrophils are additionally activated and produce bactericidal substances, such as proteases and oxygen radicals. B and T lymphocytes are stimulated for the synthesis of antibodies and cellular immune reaction. In the continuing septic process, however, apoptosis of B cells, CD4 helper cells, and follicular dendritic cells causes an anti-inflammatory immune suppression, called transient immune paralysis [9].

Activation of the complement and coagulation cascades further amplifies this chain of events. There is microvascular injury, thrombosis, and loss of endothelial integrity (capillary leak), resulting in tissue ischemia. This diffuse endothelial disruption is responsible for the multiple organ dysfunction and global tissue hypoxia that accompany severe sepsis/septic shock [10].

## Bacteriology of urinary infections and sepsis

The pathogens associated with UTIs and urosepsis have not varied greatly over the last decades and concern centers around the considerable changes in resistance patterns [1]. A continuous assessment of local patterns is important to establish the most appropriate antibiotic regimens to prevent infectious complications most efficaciously. *Escherichia coli* remains the single most common microorganism to cause urinary infection. This is followed by *Klebsiella* and *Pseudomonas*, frequently associated with stone disease. Furthermore, the increasing presence of Gram-positive bacteria such as *Enterococcus* and *Staphylococcus* should be noted [1].

DasGupta et al. reported that 40% of urology inpatients had Gram-positive organisms, with *Enterococcus* accounting for 27% [11]. Several reports have shown that other organisms have increased not only their incidence, but also their resistance to antibiotics commonly used in urology, including trimethoprim, quinolones, cephalosporins, and aminoglucosides, such as gentamicin; this is the case for *Pseudomonas aeruginosa*, methicillin-resistant *Staphylococcus aureus* [12], *Serratia* spp., and *Clostridium difficile.* Many common antibiotics once prescribed for uncomplicated urinary infection such as ciprofloxacin and trimethoprim now have high resistance rates. The rates of resistance from 2000 to 2008 to ciprofloxacin rose in Germany (2 to 21%), Spain (15 to 31%), Sweden (0 to 7%), and the UK (1 to 15%), as well as to trimethoprim in Germany (23 to 37%), Spain (25 to 37%), Sweden (9 to 17%), and the UK (13 to 46%) [13]. This rise in resistance of urinary pathogens towards quinolones has been reported worldwide and might be the consequence of its overuse due to its efficacy in treating other infections and uncomplicated UTIs, as well as its misuse as prophylaxis in some urologic diagnostic procedures. In cases of urosepsis, resistance to commonly prescribed antibiotics was high and rates ranged from 8% (imipenem) to 62% (aminopenicillin/β-lactamase inhibitors); 45% of Enterobacteriaceae and 21% of *P. aeruginosa* were multidrug-resistant [14].

## General measures of sepsis prevention in genitourinary surgical patients

In recent years, the incidence of sepsis has increased, but the associated mortality has decreased, suggesting improved management of patients [15]. Besides correct management, the role of prevention is of great importance and it is imperative to identify preoperative risk factors, apply adequate prophylaxis, and try to minimize intraoperative risks, in order to reduce the incidence of septic episodes or allow early recognition of the features that can lead to one.

The EAU in its Guidelines on Urological Infections recommends the following basic preventive measures of proven efficacy in any urologic patient undergoing surgery [4]:

- Isolation of all patients infected with multiresistant organisms to avoid cross-infection.
- Prudent use of antimicrobial agents, both in prophylaxis and in treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. It is well known that long inpatient stays prior to surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition.
- Nosocomial UTIs are promoted by bladder catheterization as well as by ureteral stenting.

- Antibiotic prophylaxis does not prevent stent colonization, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimization of breaks in the integrity of the system.
- Use of the least-invasive method to release urinary tract obstruction until the patient is stabilized.
- Attention to simple everyday techniques to ensure asepsis, including the routine use of protective, disposable gloves, frequent hand disinfection, and infectious disease control measures to prevent cross-infections.

## Preoperative evaluation

All patients who are being considered for genitourinary surgery should be evaluated with a complete medical history, physical examination, and laboratory tests, including an obligatory urine culture; this will identify those patients with a high risk for development of an infectious complication [16].

### Risk factors for infectious complication

There are well-recognized risk factors that for academic purposes can be categorized under the following headings (Table 4.1).

#### *Related to the patient*

There are several patient characteristics known to increase the risk of infectious complication after surgery. These include patients who are immunosuppressed secondary to diverse causes, among others; those with malignant or autoimmune diseases receiving chemotherapy or chronic use of corticosteroids usually have impaired infection resistance. Also patients of advanced age or poor nutritional status, with diabetes, obesity, significant kidney or liver diseases, and female patients have a higher risk [6]. Other related factors are the presence of a coexistent infection at another site at the time of surgery or prolonged hospitalization.

#### *Related to urinary tract diseases*

Urinary diseases or their management increase the possibility of colonization and chronic bacteriuria. Risk factors in urologic patients are anatomic anomalies, voiding dysfunction, urinary diversion, active UTI, obstruction of the urinary tract, stone disease, indwelling catheters, and endogenous material, such as ureteral stents and nephrostomy tubes.

Many of these patients will have a positive urine culture and must receive preoperative antibiotics appropriately tailored to culture-specific organisms; at the end of treatment urinary evaluation must be repeated. Rao et al. reported that bacteriuria and pyuria are risk factors for bacteremia; they also found that preoperative bacteriuria had a positive predictive value (PPV) of 0.53 for detection of endotoxemia, another important risk factor for the development of urosepsis [17].

#### *Related to procedure*

Any procedure performed in patients with urolithiasis has a potential risk for postoperative infection due to bacterial colonization of the urinary tract, infection stones, or urinary drainage obstruction and indwelling catheters. Prolonged surgical time, high intrapelvic pressures during endourologic procedures, such as percutaneous or retrograde renal surgeries, and bleeding during procedure carry a high risk of postoperative infection. Open or laparoscopic surgeries, which involve the gastrointestinal or genital tract, such as urinary diversions or vesicovaginal fistula repair, also should be considered high-risk procedures for infection.

These factors frequently act in an additive manner, compounding their impact. The likelihood of bacterial invasion is also affected by the amount of bacteria at the site of the surgical procedure. All procedures invading the urinary tract are considered "clean–contaminated." The likelihood of bacterial invasion is increased if bacteriuria is present or adequate wound preparation and surgical techniques are not employed [9].

**Table 4.1** Risk factors associated with postoperative infectious complications in genitourinary surgery.

| Related to patient | Related to urinary tract diseases | Related to procedure |
|---|---|---|
| Immunosuppression | Chronic bacteriuria | Stone disease management |
| Malignancy | Voiding dysfunction | Incisional therapy |
| Autoimmune diseases | Urinary diversion | Surgery of long duration |
| Chronic corticosteroid use | Obstruction | Involvement of genital tract |
| Diabetes mellitus | Stone disease | Involvement of gastrointestinal tract |
| Poor nutritional status | Indwelling catheters | Prosthesis |
| Severe kidney or liver dysfunction | Endogenous material (ureteral stents) | |
| Advanced age | Anatomic anomalies | |
| Female | Impaired urinary flow | |
| Distant coexistent infection | | |
| Prolonged hospitalization | | |

## Antibiotic prophylaxis

Prophylaxis means a brief course of antibiotics administered before or at the start of an intervention, and is used to minimize the infectious complications resulting from diagnostic and therapeutic interventions. While the rationale for the use of antibiotics is well accepted, possible side effects and development of antimicrobial resistance patterns are potential risks. Therefore, an antibiotic prophylaxis policy should be well considered and based on high levels of evidence [18].

Surgical antimicrobial prophylaxis is recommended only when the potential benefit exceeds the risks and anticipated costs; it has been demonstrated in a variety of settings that surgical antimicrobial prophylaxis, by reducing the incidence of surgical site infections, reduces costs. Conversely, excess and/or inappropriate antimicrobial prophylaxis increases costs, which is reversed by measures to improve compliance with evidence-based recommendations [19]. A multicenter study looked a the rate of antibiotic resistance, daily antibiotic dose, and cost after implementation of antibiotic guidelines. The rate of resistance of *E. coli* to piperacillin/tazobactam (9.1 vs. 5.4%), gentamicin (18.3 vs. 11.2%), and ciprofloxacin (32.3 vs. 19.1%) decreased significantly after guideline introduction. The defined daily dose (DDD) use of ciprofloxacin fell from 4.2 to 0.2 DDD per 100 patient days after implementation, and antibiotic drug costs (€76 980 vs. €36 700) and costs related to postoperative infections (€45 870 vs. €29 560) decreased following introduction of the guideline [20].

In considering prophylactic treatment, the surgical site and the properties of the antimicrobial agent should be taken into account. The agent should achieve serum and tissue levels that exceed the minimum inhibitory concentration for organisms characteristic of the operative site. Furthermore, the optimal agent should have a long half-life so as to maintain sufficient serum and tissue concentrations for the duration of the procedure without the need for redosing. It should be safe, inexpensive, and unlikely to promote bacterial resistance [3].

For prophylactic antimicrobial administration to be optimally effective, timing and dosing are critical. Infusion of the first dose should begin within 60 minutes of the surgical incision (with the exception of 120 minutes for intravenous fluoroquinolones and vancomycin). Correct dosing is equally important. Some drugs should be adjusted to the patient's body weight. Oral administration is as effective as the intravenous route for antibiotics with sufficient bioavailability. This is recommended for most interventions, when the patient can easily take the drug between 1 and 2 hours before intervention. Additional doses are required intraoperatively if the procedure extends beyond two half-lives of the initial dose [21]. With few exceptions, the published literature suggests that antimicrobial prophylaxis is unnecessary after wound closure or upon termination of an endoscopic procedure; in most cases, antimicrobials should be given in a single dose, or at least discontinued within 24 hours of the end of the procedure [22].

Three circumstances in which a longer duration of antimicrobials is frequently considered include the placement of prosthetic material, the presence of an existing infection, and the manipulation of an indwelling tube [23]. In cases where an existing infection is present, a therapeutic course of antimicrobials should be administered in an attempt to sterilize the field. In the absence of pre-existing bacterial colonization, there is no evidence that prophylaxis should extend beyond 24 hours following a procedure. In cases where prolonged catheterization follows the procedure (e.g. radical prostatectomy), antimicrobial therapy at the time of catheter removal may be therapeutic rather than prophylactic, since colonization has likely occurred. An alternative is to culture the urine 24–48 hours prior to the intended catheter removal, and administer culture-directed therapy. This is not practical in cases of catheterization for only 48–72 hours. An option then is to administer antimicrobial treatment empirically [3].

The use of preoperative antibiotics can reduce the risk of surgically related infection. Table 4.2 summarizes the recommendations for best practice in antibiotic prophylaxis in urologic surgery from the published EAU and AUA guidelines [3, 4].

## Preoperative antibiotics and preventive measures of sepsis in specific procedures

### Transurethral surgery

#### Transurethral resection of prostate

UTIs and other infectious complications can be present in 1–26% of patients treated with transurethral resection of prostate (TURP). Risk factors associated with postoperative bacteriuria are operative time, disconnection of the closed urine drainage system, prolonged postoperative catheterization (≥3 days), and preoperative catheterization (within 1 month prior to surgery) [24, 25]. TURP is the most studied procedure regarding the use of antibiotic prophylaxis. Two large meta-analyses have been published which include 38 and 32 randomized clinical trials respectively, and both concluded that the benefit obtained from antibiotic prophylaxis in TURP is sufficiently well demonstrated [26, 27]. The incidence of bacteriuria is reduced (26 to 9%), as is that for clinical sepsis

**Table 4.2** Recommended antimicrobial prophylaxis in genitourinary surgery and procedures. Data from [3, 4].

| | Indication | | Antibiotic scheme | | | |
|---|---|---|---|---|---|---|
| **Procedure** | **AUA** | **EAU** | **First choice** | **Alternative** | **Duration** | **Remarks** |
| **Diagnostic procedures** | | | | | | |
| Cystography, cystoscopy, ureteroscopy, urodynamics | If risk factors | If risk factors | Fluoroquinolone or 2nd-generation cephalosporin or TMP–SMX | Aminoglycoside ± ampicillin or amoxicillin/clavulanate | ≤24 hours | If urine culture is negative, antimicrobial prophylaxis is not necessary |
| Prostate biopsy | All | All | Fluoroquinolone or TMP–SMX | Aminoglycoside + metronidazole or clindamycin | ≤72 hours | |
| **Endourologic surgery and shock-wave lithotripsy** | | | | | | |
| Shock-wave lithotripsy | All | If risk factors | Fluoroquinolone or TMP–SMX or 2nd/3rd-generation cephalosporin | Aminoglycoside ± ampicillin or amoxicillin/clavulanate | ≤24 hours | Patients with ureteral stent, nephrostomy obstruction and infection stone |

TURP, transurethral resection of prostate; TURBT, transurethral resection of bladder tumor; TMP–SMX, trimethoprim–sulfamethoxazole; BLI, β-lactamase inhibitor.

### Box 4.1 Key points in prevention of infection/sepsis in transurethral resection of prostate (TURP)/transurethral resection of bladder tumor (TURBT).[a]

1) Identify high-risk patients.
2) Treat any positive preoperative urine cultures.
3) Obtain a preoperative negative urine culture (ideally).[b]
4) Antimicrobial prophylaxis in all cases:[c]
   - maintain closed urinary drainage system
   - avoid prolonged catheterization (>3 days).

[a] Applicable to other transurethral procedures with manipulation.

[b] With chronic bacteriuria or in catheterized patients administer 3–7 days of culture-sensitive antibiotics before surgery.

[c] For TURBT, EAU guidelines recommend antimicrobial prophylaxis only in the presence of risk factors or large and/or necrotic tumors.

(4.4 to 0.7%). Wagenlehner et al., in a large, prospective multicenter study, compared two antibiotics regimens with a control group; they found that the patients receiving antibiotics showed lower levels of bacteriuria compared with controls and demonstrated that the presence of bacteriuria post TURP (CFU $>10^4$/ml) is a risk factor for infectious complications [28]. There was no statistical difference between antibiotic regimens. Bacteriuria is not considered to be an infectious complication but the last study showed that there is a correlation between bacteriuria and the development of infectious complications.

The AUA guidelines recommend the use of antimicrobial prophylaxis in all patients. The suggested antimicrobial prophylaxis is fluoroquinolone or trimethoprim–sulfamethoxazole as antimicrobial of first choice, and alternatively a first- or second-generation cephalosporin, aminoglycosides ± ampicillin or amoxicillin/clavulanate, before the start of TURP and until less than 24 hours postoperatively [3]. The EAU guidelines recommend a very similar antibiotic regimen in all patients other than those at low risk or with a small prostate [4] (Box 4.1).

#### Transurethral resection of bladder tumor

The AUA guidelines recommend the same regimen of antimicrobial prophylaxis mentioned above for TURP in all patients undergoing transurethral resection of bladder tumor (TURBT). In contrast, the EAU guidelines recommend that antimicrobial prophylaxis for TURBT is unnecessary unless the patient has some risk factors for infectious complications, or a large tumor requiring a prolonged resection time, or a necrotic tumor. Scientific evidence supports the recommendation by the EAU in two studies that did not show any difference between antibiotics and placebo in terms of reduction of the rate of bacteriuria [29, 30]. Yokoyama et al., in a prospective, randomized study in patients with no risk factors for complications, corroborated these findings; no differences were found in terms of infectious complications between groups given antibiotics or placebo. The authors concluded that antibiotics might be deferred and only given to patients who develop postoperative infections [31]. In contrast to this, a retrospective review of patients undergoing TURBT looked at factors that lead to unplanned hospital readmission rates. On multivariable analysis, the use of preoperative antibiotics was found to be significant [32]. This finding is likely related to development of hematuria related to UTI but was not specifically elucidated. There is little evidence for any benefit of antibiotic prophylaxis in TURBT. However, antibiotic prophylaxis should be considered in patients with large tumors with a prolonged resection time, and those with risk factors for infection [30, 33, 34].

#### Other transurethral procedures

Other transurethral procedures involving manipulation, like bladder biopsy, laser prostatectomy, and internal uretrotomy, may be similar in terms of tissue trauma, and the AUA guidelines suggest that data regarding TURP and TURBT could be extrapolated to these procedures.

## Management of nephrolithiasis

Although infection or sepsis may occur despite a sterile preprocedure urine culture, every effort should be made to sterilize the urinary tract before instrumentation. Preoperative treatment with culture-specific antibiotics and subsequent documentation of successful treatment is imperative. While having a negative preoperative urine culture is desirable for all endourologic procedures, this is not always possible, mainly because of stone or urinary tract colonization. In these cases, oral culture specific antibiotic therapy should start at least 1 week before the planned procedure or intravenous therapy at least 24 hours prior to the planned procedure.

Patient-related risk factors associated with the development of postoperative infections include:

- immunosuppression secondary to malignancy, or autoimmune diseases
- chemotherapy or chronic use of corticosteroids
- diabetes mellitus
- advanced age, poor nutritional status, obesity
- significant kidney or liver diseases
- female patients
- presence of a coexistent infection at another site at the time of surgery
- prolonged hospitalization.

Whereas urinary tract-related risk factors include:

- anatomic anomalies and voiding dysfunction
- urinary diversion
- presence of obstruction to the urinary tract
- presence of indwelling catheters, ureteral stents, nephrostomy tubes.

### Shock-wave lithotripsy

The use of prophylactic antimicrobial treatment in patients who undergo shock-wave lithotripsy (SWL) is debated in the literature. The AUA Best Practice Policy guidelines on antibiotic prophylaxis recommends preoperative antibiotic prophylaxis for all patients undergoing SWL [3]. This recommendation was based on a 1997 meta-analysis by Pearle and Roehrborn [35] combining data from eight randomized controlled trials. This study found that the post-SWL urinary tract infection rate for the placebo/no-prophylaxis patients was 5.7% (range, 0–28%) compared to 2.1% (range, 0–7.7%) for patients who were given preprocedural prophylaxis. The relative risk of UTI with prophylaxis was 0.45 ($P = 0.0005$).

The EAU based their contemporaneous recommendations [4] on a narrower list of randomized control trials that focused on the effects on antibiotic prophylaxis rather than the treatment itself. Along with follow-up studies they found that the rates of post-SWL symptomatic UTI and asymptomatic bacteriuria were low both with and without prophylaxis [18]. Their ultimate recommendation is against antibiotic prophylaxis prior to SWL in patients without stents or positive urine cultures.

Since the time of the original AUA guideline statement, Lu and colleagues re-examined the available data in their own meta-analysis including nine randomized trials (1364 patients) [36]. Lu showed that antibiotic prophylaxis did not significantly reduce the risk of fever (relative risk [RR] = 0.36, $P = 0.31$) or overall asymptomatic bacteriuria (RR = 0.77, $P = 0.17$). There was a trend toward protection against UTI (RR = 0.54, $P = 0.05$); however, there was no difference in UTI rates for patients with preoperative ureteral stents (RR = 0.85, $P = 0.75$).

Duvdevani et al. has supported the recommendation that antibiotics prophylaxis is only indicated in patients with risk factors such as those listed in Table 4.1 or those undergoing a concomitant urologic procedure at the time of the SWL [37]. Although the rate of bacteremia post-SWL is reported to be as high as 14%, the rate of sepsis is less than 1%, and the use of prophylaxis remains controversial [38]. The key points in prevention are listed in Box 4.2.

Thus in light of the most recent publications, prophylactic antibiotics are recommended only in high-risk stone groups with infected stones, recent instrumentation, nephrostomy tubes, positive urine cultures, and a history of recent UTI or sepsis. In addition, special consideration should be given to certain high-risk patient groups such as those with as advanced age, anatomical anomalies of the urinary tract, poor nutritional status, chronic smokers, chronic steroid users, immunodeficiency, externalized catheters, and prolonged hospitalization. In general, SWL should only be performed if the patient's urine is sterile and when there is no distal obstruction to minimize infective complications. Currently, prophylactic antibiotics should be considered only in high-risk patients.

### Box 4.2 Key points in prevention of infection/sepsis in SWL.

1) Identify risk factors.
2) Rule out active UTI prior to the procedure.
3) Obtain preoperative negative urine culture (ideally).[a]
4) Antimicrobial prophylaxis if one of the following:[b]
   - obstruction
   - presence of an indwelling stent or catheter
   - infection stones
   - periprocedure stone or urologic manipulation (stone mobilization, double-J stent insertion).

---

[a] In bacterial persistence or chronic bacteriuria administer at least 3 days of culture-specific antibiotics before SWL.

[b] AUA guidelines recommends antimicrobial prophylaxis in all cases.

### Ureteroscopy

A 2003 randomized control trial by Knopf et al. which included 113 patients found a single prophylactic oral dose of fluoroquinolone prior to ureteroscopy reduced the incidence of postoperative bacteriuria (1.8% vs. 12.5%, $P = 0.02$) [39]. There were, however, no incidences of symptomatic UTI. This study guided the AUA Best Practice Policy in recommending antibiotic prophylaxis prior to ureteroscopy for the management of stone disease [3]. The guideline committee states that the potential risk of bacteriuria is 30% and UTI ranges from 4 to 25% without prophylaxis. Practice studies have shown that there is no difference in efficacy between oral fluoroquinolone and intravenous cefazolin [40].

With regard to postoperative prophylaxis for patients with stents, Ramaswamy and Shah retrospectively reviewed their experience between two groups that had received different post-procedural prophylaxis [41]. The first group was covered with fluoroquinolones for 1 week post-ureteroscopy until stent removal, while the second group received 3 days of cephalexin immediately prior to ureteral stent removal within 1 week of surgery. They observed no differences in asymptomatic bacteria or symptomatic UTI rates (2% for both groups). Unfortunately, this series did not examine whether any antibiotics were indicated post-ureteroscopy or not.

A Korean group reviewed their experience with infectious complications following ureteroscopy and identified several risk factors [42]. They noted an overall UTI rate of 3.8%. Furthermore, they found hydronephrosis, bacteriuria, and an indwelling ureteral stent or nephrostomy tube was associated with an increased risk of post-procedural fever. Administration of antibiotics after the procedure was not as effective as preprocedural prophylaxis. Martov et al. assessed the CROES database and examined the rate of infection after ureteroscopy [43]. They noted that the overall rate of infection for patients with negative urine culture was only 2.2% and there was no significant difference in infection rates for patients who did not receive prophylactic antibiotics. Current AUA and EAU recommendations for antimicrobial prophylaxis are given in Table 4.2.

As with other endourological procedures, the routine use of antimicrobial prophylaxis for ureteroscopy in patients with a sterile preoperative urine culture is controversial. Assessment of urine for sterility by midstream urine specimen (MUS) culture and sensitivity (C&S) is recommended by most endourologists as an essential prerequisite for endoscopic stone treatment. Nevertheless, MUS cultures do not always correlate with obstructed urine or stones, and sepsis may present in 1% of cases which have a negative MUS culture. Mariappan et al., in a prospective study, cultured MUS, renal pelvic urine, and obstructing ureteric stones from patients who had undergone ureteroscopic lithotripsy [44]. Clinical bacteremia was seen in 19%. Of these, 58.3% developed features of systemic inflammatory response syndrome (SIRS). Blood and stone C&S were positive in 25% of cases and pelvic urine C&S was positive in 66.7%, but none had a positive MUS C&S ($P = 0.04$).

Moreover, there has been increased interest in stone cultures and their increased sensitivity over voided urine in predicting UTI or sepsis. The bulk of the literature has focused on stone cultures in patients undergoing percutaneous nephrolithotomy (PCNL). However, in a recent publication, one group also examined their role in patients undergoing ureteroscopic procedures. Eswara and colleagues retrospectively reviewed their experience with stone cultures in patients undergoing ureteroscopy ($n = 274$) or PCNL ($n = 54$) [45]. They found that while preoperative urine cultures were only positive at some point in 7% of patients, stone cultures were positive in 29%. Their overall sepsis rate was about 3–4% for all patents. In patients with positive stone cultures, the sepsis rate was significantly higher at 8% compared to only 1% in those who had negative stone cultures. Ultimately, urine cultures had a sensitivity of 11% versus 64% in stone cultures and there was a concordance of 64% between the stone culture pathogen and the one causing sepsis compared to only 9% of preoperative urine cultures. Despite the correlation of stone cultures and postoperative infection, their utilization in guiding clinical practice is limited in that it takes several days following the removal of the stone for cultures to results. They are most helpful following the development of UTI to help guide antibiotic choice.

As a consequence of the potential risk for infection from the presence of infected stones, antibiotic prophylaxis is indicated for any ureteroscopic intervention performed for the treatment of urinary tract calculi. Indications for antibiotics are less clear for diagnostic ureteroscopy or treatment of tumors. The risk of infection and sepsis, albeit low (3.4 and 0.3–2%, respectively), outweighs the potential benefits, such as cost savings, that may be associated with no antibiotic administration for therapeutic proposes [46].

Modifiable intraoperative factors may influence infectious complications (Box 4.3). During ureteroscopy, the hydrostatic pressure generated by the irrigation fluid results in bacterial and endotoxin translocation into the systemic circulation; therefore, a low-pressure irrigation system can reduce the incidence of systemic infection. Only enough irrigation to maintain adequate visibility should be used, and renal pressure should be kept as low as possible with the use of a ureteral access sheath (UAS) or angiographic catheter, or periodic drainage of the collecting system through the ureteroscope. In addition, continuous or intermittent bladder drainage with a small-caliber bladder catheter will help maintain low intrarenal pressures during ureteroscopy [46]. Auge et al. found that by using a UAS during ureteroscopic stone surgery, pressures in the urinary tract could be significantly reduced. Flexible ureteroscopy was performed with and without the aid of the UAS while pressures were measured via the nephrostomy tube connected to a pressure transducer. With the ureteroscope positioned in the distal ureter, the mean intrarenal pressure without the UAS was 60 compared with 15 mmHg with the UAS; with the ureteroscope in the renal pelvis the pressures were 94.4 and 40.6 mmHg, respectively [47].

### Percutaneous renal surgery

PCNL has become the treatment of choice for large and complex (staghorn) stones. The most common composition for staghorn stones is struvite [48], which results from the presence of urea-splitting organisms in the urinary tract. Large non-struvite stones may also harbor bacteria. Additionally, PCNL, while minimally invasive, still traverses through skin, retroperitoneal, and renal tissue to access the urinary tract and stone and utilize large volumes of irrigation relative to ureteroscopy. These factors, taken together, make a strong case for preoperative

### Box 4.3 Key points in prevention of infection/sepsis in therapeutic ureteroscopy.

1) Identify high-risk patients.
2) Treat preoperative positive urine cultures:
   - *never* perform stone manipulation or incision therapy in active UTI
   - relieve urinary obstruction, treat infection, and carry out a staged treatment.
3) Ensure a preoperative negative urine culture (ideally).[a]
4) Antimicrobial prophylaxis in all cases.
5) Maintain low intrarenal pressure during procedure. Options:
   - periodic drainage through ureteroscope or use of ureteral access sheath or angiographic catheter
   - continuous or intermittent bladder drainage.

[a] In chronic bacteriuria administer at least 3 days of culture-sensitive antibiotics before instrumentation.

### Box 4.4 Key points in prevention of infection/sepsis in percutaneous renal surgery.

1) Identify high-risk patients.
2) Treat preoperative positive urine cultures:
   - *never* perform stone manipulation or incision therapy when there is active UTI!
3) Ensure sterile urine preoperatively (ideally).[a]
4) Antimicrobial prophylaxis in all cases.
5) Stop procedure if purulent fluid is obtained at puncture, leave a nephrostomy tube, and stage treatment.[b]
6) Maintain low intrarenal pressure during procedure:
   - use only enough irrigation to maintain adequate visibility
   - use a wide renal access sheath, ideally 4 Fr wider than nephroscope.
7) Limit quantity of irrigation fluid and operative time.

[a] In chronic or asymptomatic bacteriuria administer at least 7 days of culture-sensitive antibiotics before surgery.
[b] Obtain pelvic urine culture and treat infection completely.

antibiotic prophylaxis. It is generally agreed that patients who are scheduled for PCNL must have a negative urine culture before surgery. Unfortunately, this is not always possible to adhere to because of stone or urinary tract colonization; in these patients, appropriate antibiotic therapy should start at least 1 week before the planned procedure (Box 4.4).

The practice of prophylaxis was reinforced by the CROES group, who retrospectively identified 162 patients from multiple institutions who underwent PCNL without preoperative antibiotics and matched them to patients who did receive antibiotics [49]. All patients had negative preoperative urine cultures and matching was based on infectious risk factors such as diabetes, nephrostomy tubes, and staghorn stones. They found that antibiotic prophylaxis led to fewer fevers (2.5 vs. 7.4%) and other complications (1.9 vs. 22%) and higher stone-free rate (86.3 vs. 74%).

Gutierrez et al. assessed 5354 consecutive patients undergoing PNCL from the CROES database between 2007 and 2009 [50]. Some 10.4% of the patients developed a fever: 8.8% of those with negative preoperative cultures, and 18.2% with positive preoperative cultures. In this study, factors found on multivariate analysis to increase the risk of fever included a positive urine culture (adds ratio [OR] 2.12), staghorn calculus (OR 1.59), preoperative nephrostomy (OR 1.61), lower patient age (OR 0.99 for each year), and diabetes (OR 1.38).

Other studies that compared limiting antibiotics to preoperative prophylaxis with continuing until nephrostomy tube removal found no difference in infection-related outcomes [51–53]. Bag and colleagues randomized high-risk patients (stone ≥2.5 cm and/or hydroureteronephrosis) to immediate preoperative antibiotic prophylaxis versus 1 week of nitrofurantoin plus prophylaxis prior to PCNL. The patients who received nitrofurantoin were more likely to have sterile pelvic urine (RR = 4.95) and stone cultures (RR = 3.64), and less likely to have endotoxemia (RR = 0.22) or experience SIRS (RR = 0.31) [54].

The published literature suggests that antimicrobial prophylaxis is unnecessary after wound closure or on termination of an endoscopic procedure, but because PCNL can be associated with a pre-existing infection, infectious stone, or manipulation of an indwelling catheter the subsequent course of antimicrobials that is therapeutic rather than prophylactic might extend beyond 24 hours from the conclusion of the procedure. In the absence of pre-existing bacterial colonization, there is no evidence that prophylaxis should extend beyond 24 hours. Deshmukh et al. [22] studied whether compliance with AUA guidelines for prophylactic antibiotics increased infection rates compared to those who received 5–7 days of antibiotics. No difference was seen in infection rates for those who received prolonged antibiotics versus those who only received ≤24 hours of antibiotics.

In cases where prolonged catheterization follows the procedure (i.e. nephrostomy tube), antimicrobial therapy at the time of catheter removal may be therapeutic rather than prophylactic, because colonization likely has occurred. A recommended antimicrobial regimen is given in Table 4.2.

Results of urine cultures from patients with stones are not predictive of stone bacteriology, especially in those with struvite stones. Therefore, this group should receive broad-spectrum antibiotic therapy that is specific to the cultured bacteria but also likely to be effective against urease-producing organisms residing in the stone. Mariappan et al. demonstrated that stone and pelvic urine cultures obtained during surgery are better predictors of potential urosepsis than bladder MSU [55]; they found that bladder urine cultures were positive in 11.1% of cases versus 35.2 and 20.4% of stone and pelvic urine cultures, respectively. Stone culture showed the greatest positve predictive value (0.7). Infected bladder urine did not always carry identical bacteria to those found in the upper tract. Patients with pelvic or stone positive cultures showed a relative risk for urosepsis at least four times greater than the rest of the cohort. In this study, bladder urine did not predict SIRS. Also, they found that preoperative hydronephrosis and stones larger than 20 mm correlated with positive stone and pelvic urine cultures.

Renal pelvic pressure (RPP) greater than 30 mmHg has also been shown to result in pyelovenous–lymphatic backflow. Troxel and Low, in a prospective study that included 31 patients, found that during PCNL pressures greater than 30 mmHg were recorded in only eight (26%) patients and no association was seen between RPP and postoperative fever [56]. Contrary to this, Zhong et al. demonstrated that mean intrapelvic pressure greater than 20 mmHg and accumulated time of RPP greater than 30 mmHg may cause enough backflow to contribute to bacteremia and postoperative fever [57]. Low RPP during surgery is achieved using an open low-pressure access system, such as operating through an Amplatz sheath (operating instrument 4 Fr sizes smaller than the access sheath). Inflow of irrigant should be at gravity and never pressurized. We also recommend the use of forced diuresis (furosemide 20 mg at the beginning of irrigation and every 60 minutes of surgery and irrigation time) to reduce further the pyelorenal reflux that potentially causes fluid overload and bacteremia. Others factors that have been related to postoperative fever and risk of bacteremia are long operative time, large stone burden, and large amounts of irrigating fluid.

Manipulation of infected stones can cause sepsis due to endotoxemia. McAleer et al. measured endotoxins levels in renal stones and found markedly higher levels in infection stones [58]. Interaction of bacteria with different intracorporeal lithotripters may have antibacterial effects. *In vitro* studies have shown a decrease of bacteria viability after use of intracorporeal lithotripsy and laser [59]. We reported that extracorporeal shock-wave or intracorporeal lithotripsy, using all the alternatives currently available, are significantly effective at reducing the viability of bacteria located inside artificial stone models, including struvite stone models infected with *Proteus mirabilis* [60–62]. Whether this bactericidal effect is desirable is still to be answered, because reduction in the number of bacteria may represent an increase in the presence of proteins/endotoxins liberated from bacterial cell lysis, therefore increasing the risk of urosepsis.

In the presence of an obstruction at the ureteropelvic junction or intrarenal segments (stone, stricture, or tumor), infected urine may be encountered despite previous negative cultures of the voided urine. In such instances, treatment has to be postponed, the urine cultured, and the renal collecting system drained under antibiotic coverage until eradication of the infection is documented. According to Ramsey et al. in a recent evidence-based review [63], the effects on the resolution of infected hydronephrosis are similar if a ureteral stent or a nephrostomy tube is used; nevertheless, Mokhmalji et al., in a prospective randomized study, reported prolonged fever and catheter placement time in the group of patients treated with ureteral stent, and suggest that percutaneous nephrostomy is superior to ureteral stents for diversion of hydronephrosis [64].

Small case series have been reported that explore the possibility of continuing the surgery even if purulent urine is encountered incidentally. Aron et al., in a group of 19 patients, reported no difference regarding the incidence of postoperative fever or sepsis between patients with one-stage versus staged surgery with collecting system drainage and 3–7 days of intravenous antibiotic coverage before a second procedure [65]. Hosseini et al. divided 45 patients into two groups: in group 1 ($n = 29$) stones were removed during the first session and in group 2 ($n = 16$) a nephrostomy tube remained in place and stone removal was accomplished 3–5 days later when results of urine and nephrostomy fluid cultures were negative [66]. They reported no intraoperative or postoperative complications, other than transient fever in 10.3 and 12.5% in groups 1 and 2, respectively. In spite of these recent reports, there are neither sufficient evidence nor well-designed clinical trials to recommend other conduct than performing a staged procedure with drainage and broad-spectrum antibiotic therapy until infection has resolved.

Therefore, these studies suggest that when the preoperative urine culture is negative, a single dose of antibiotics appears to be as effective in preventing postoperative infections as multiple doses irrespective of the type of antibiotic used. A systematic review published in 2008 concluded that in the presence of a negative preoperative culture there was a low evidence of postoperative UTI, suggesting a more favorable outcome after PNL by using antibiotic prophylaxis and that, when prophylaxis was used, there was no advantage for any specific antimicrobial regimen [18].

## Open and laparoscopic urologic surgery

Surgical wound classification into the categories clean, clean–contaminated, contaminated, and dirty seems as relevant to urologic surgery as it is for general surgery [67].

**Clean surgery**

This category involves surgery performed in uninfected tissues without opening of the urinary tract and with primary closure of the wound. Montgomery et al., in a prospective but nonrandomized trial, compared 424 hand-assisted laparoscopic nephrectomies with and without antimicrobial prophylaxis (cephalosporin preoperatively), and found that omission of antibiotic prophylaxis was significantly associated with an increased rate of incision site infections (13 vs. 5.4%) [68]. Steiner et al. randomized a group of 83 patients undergoing open transabdominal radical nephrectomy to a single dose of intravenous third-generation cephalosporin ($n=39$) versus no antimicrobial prophylaxis ($n=44$) and found a significantly lower overall infection rate in the prophylaxis group (7.7 vs. 27.3%) [69]. Togo et al. [70] evaluated 4677 consecutive cases of which 1277 were clean. In the group that received a single dose of prophylactic antibiotic, the rates of surgical site infection, UTI, and remote infection were all 1%.

**Clean–contaminated surgery**

In this category, the urinary tract is entered under controlled conditions and there are no infected tissues or bacteriuria. Surgery involving bowel tissue is also classified as clean–contaminated. According to the EAU guidelines for UTI, prophylactic antibiotics are not recommended for open procedures that do not involve bowel segments, except in patients who are at increased risk of infection, as occurs with long-term urinary drainage. The expected rate of febrile UTI in surgeries that enter the urinary tract is close to 10% without prophylaxis; antimicrobial prophylaxis can be expected to significantly reduce this rate to 2–3% [71]. Regarding the optimal duration of perioperative prophylaxis, one randomized controlled trial confirmed that 1 day of intravenous second-generation cephalosporin was as effective as 4 days of the same agent in the prevention of postoperative infections after radical prostatectomy [72]. Stranne et al. also found in a prospective study that a single dose of antibiotic (a quinolone) given before radical retropubic prostatectomy appears to be sufficient prophylaxis [73]. Togo found the rates of surgical site infection, UTI, and remote infection were 3, 3, and 2% respectively after having received a single dose of prophylactic antibiotic [70].

**Contaminated and dirty surgery**

The contaminated category includes the presence of an untreated infection, including UTI, or the gross spillage of fecal matter. When purulence is present, the surgery is labeled as dirty. In *contaminated* and *dirty* operations, antimicrobial agents are given with a therapeutic intention. Infected urine is a very high risk factor for both surgical site infections in, for example, open prostatectomy, and febrile UTI after TURP. Casey et al. reported an incidence of infectious complication of 20% in patients with chronic bacteriuria undergoing major urologic surgery, and they found that wound infections were as common in patients whose urine cultures revealed multiple unsuspected organisms as in those who were resistant to the perioperative antibiotics [74]. Patients with an indwelling catheter, nephrostomy tube, or other stent device should be considered as having bacteriuria and must be treated in advance (between 3 and 7 days prior to the procedure) in order to favor sterile urine at the time of surgery. The patient should be covered well beyond the intervention (7–10 days or longer), depending on the type of operation and patient factors [75]. Since infectious complications are potentially serious when they involve prosthetic material, antibiotic coverage is advocated irrespective of surgical category [67]. The rates of surgical site infection, UTI, and remote infection were found to be 17, 30, and 10% respectively for clean–contaminated cases in which a single dose prophylactic antibiotic was given [70].

## Use of antibiotics in patients with indwelling catheters, stents, and drainage tubes

The most important risk factor in the development of catheter-associated bacteriuria is the duration of catheterization. Most episodes of short-term catheter-associated bacteriuria are asymptomatic and are caused by a single organism. Multiple organisms tend to be acquired in patients catheterized for more than 30 days. The clinician should be aware of two priorities: the catheter system should remain closed and the length of catheterization should be minimal. While the catheter is in place, systemic antimicrobial treatment of asymptomatic catheter-associated bacteriuria is not recommended, except for some special cases. Routine urine culture in an asymptomatic catheterized patient is also not recommended because treatment is in general not necessary. Antibiotic treatment is recommended only for symptomatic infections [76].

Long-term antibiotic suppressive therapy is not effective in this group of patients. Antibiotic irrigation of the catheter and bladder is also of no advantage. Routine urine cultures are not recommended if the catheter is draining properly. A minority of patients can be managed with the nonreturn (flip) valve catheter, which avoids the need for a closed drainage bag. Such patients may exchange the convenience of on-demand drainage for an increased risk of infection.

Alternatives to indwelling urethral catheters that are less prone to cause symptomatic infection should always be considered. In selected patients, suprapubic catheters, condom drainage systems, and intermittent catheterization are preferable to indwelling urethral catheters [4]. Intermittent catheterization is recommended whenever the patient is able to self-practice this alternative. Prophylactic antimicrobials have not been demonstrated to be beneficial in patients undergoing clean intermittent catheterization [75]. The rate of bacteriuria even in short-term catheterized patients is 5–10% for each day that the catheter is in place [77].

When continuous urinary drainage is required after surgery, perioperative antibacterial prophylaxis is not recommended unless a complicated infection requiring treatment is suspected. Asymptomatic bacteriuria (bacterial colonization) is only to be treated prior to surgery or after removal of the drainage tube. Treatment of a patient at the time of removal of an external urinary catheter should be based on culture-directed antimicrobials. An analysis in the Cochrane Database of Systematic Reviews concluded that there is limited evidence that antimicrobials during the first three postoperative days, or from postoperative day 2 until catheter removal, reduces the rate of bacteriuria and other signs of infection in surgical patients [78].

In patients with indwelling double-J stents, two randomized controlled trials showed that the rate of bacterial colonization depends directly on underlying pathologies, time of stenting, and female sex [79, 80]. Low-dose antibiotics for patients with temporary double-J stents are not recommended and have been shown to increase the risk of acquiring bacterial resistance [81]. Recent advances in stent design have lead to the development of some drug-eluting catheters with the aim of reducing the biofilm and thus the stent colonization. In a rabbit model, triclosan reduced bacterial growth and *P. mirabilis* survival, preventing stent-related UTIs [82]; unfortunately these stents are not commercially available.

## Postoperative sepsis: early identification and initial treatment

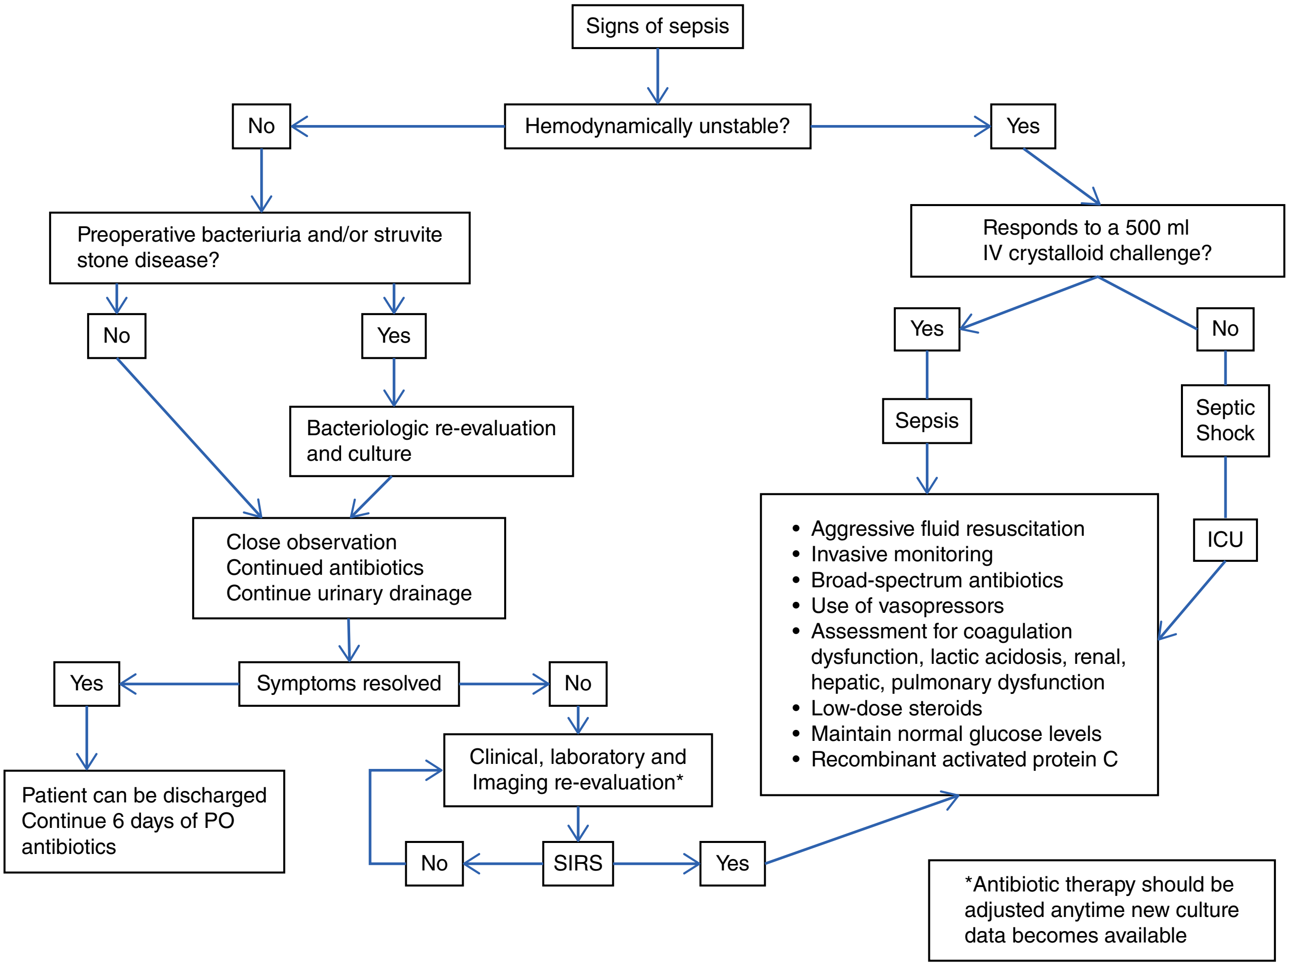
Early recognition and management of sepsis optimizes outcome. Therefore, patients in whom this problem is suspected after genitourinary surgery should be prioritized and receive timely care. To diagnose sepsis and severe sepsis/septic shock as early as possible, it is necessary to have clear definitions of infection, organ dysfunction, and global tissue hypoxia, and to recognize the clinical and laboratory findings that are indicative of these conditions.

Sepsis is defined as the presence of SIRS caused by a documented or suspected infection. SIRS is defined as the presence of two or more of the following: (i) temperature greater than 38 °C or less than 36 °C; (ii) heart rate greater than 90 beats/minute; (iii) respiratory rate greater than 20 breaths/minute (or $P_aCO_2 < 32$ torr); and (iv) white blood cell count greater than 12 000/mm$^3$ or greater than 10% immature band forms. Severe sepsis is defined as the presence of sepsis and one or more organ dysfunctions. Organ dysfunction can be defined as acute lung injury, coagulation abnormalities, thrombocytopenia, altered mental status, renal, liver, or cardiac failure; or hypoperfusion with lactic acidosis. Septic shock is defined as the presence of sepsis and refractory hypotension, i.e. systolic blood pressure less than 90 mmHg and unresponsive to a crystalloid fluid challenge of 500 ml.

As mentioned above, clinical and laboratory recognition of septic problems is mandatory. Procalcitonin is a propeptide of calcitonin, but lacks hormonal activity. During generalized infections with systemic manifestations, its level may rise considerably. In contrast, during severe viral infections or inflammatory reactions of noninfectious origin, procalcitonin levels show little or only a moderate increase in levels. Its exact site of production during inflammatory response is still unknown. The documentation of high levels of early biochemical markers, such as procalcitonin and protein C, in the initial postoperative period may help identify a severe inflammatory response to surgical stress from bacteremia, SIRS, or sepsis/septic shock, and prompt the institution of adequate and opportune therapeutic measures [83].

Cytokines are involved in the pathogenesis of sepsis syndrome. They are peptides that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including macrophages, monocytes, and endothelial cells, in response to various infectious stimuli. When they become bound to specific receptors on other cells, cytokines change their behavior in the inflammatory response. The complex balance between pro and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial proinflammatory mechanism. Other cytokines that are associated with sepsis are interleukins (IL-1, 6, and 8) and TNF-α. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a nonregulated and excessive activation of inflammation. The mechanisms of organ failure and death in patients with sepsis remain only partial understood [84].

Appropriate therapy is a continuum of infection management ranging from drainage (maintaining indwelling catheter or opening the nephrostomy tube in cases of percutaneous renal surgery), broad-spectrum antibiotics, aggressive fluid resuscitation, and invasive monitoring with medical management in the intensive care setting until the causative agent is found and eradicated (Figure 4.1).



Signs of sepsis
Hemodynamically unstable?
No
Yes
Preoperative bacteriuria and/or struvite stone disease?
No
Yes
Bacteriologic re-evaluation and culture
Close observation
Continued antibiotics
Continue urinary drainage
Symptoms resolved
Yes
No
Patient can be discharged
Continue 6 days of PO antibiotics
Clinical, laboratory and Imaging re-evaluation*
SIRS
No
Yes
Responds to a 500 ml IV crystalloid challenge?
Yes
No
Sepsis
Septic Shock
ICU
• Aggressive fluid resuscitation
• Invasive monitoring
• Broad-spectrum antibiotics
• Use of vasopressors
• Assessment for coagulation dysfunction, lactic acidosis, renal, hepatic, pulmonary dysfunction
• Low-dose steroids
• Maintain normal glucose levels
• Recombinant activated protein C
*Antibiotic therapy should be adjusted anytime new culture data becomes available

**Figure 4.1** Postoperative management of a patient suspected of or diagnosed with sepsis. ICU, intensive care unit; IV, intravenous; PO, *per os*.

Continuous monitoring of vital signs, pulse oximetry, urine output, and initial laboratory testing to assess the severity of global tissue hypoxia and organ dysfunction, including assessment for lactic acidosis, renal and hepatic dysfunction, acute lung injury, and coagulation abnormalities, should be instituted as soon as possible in patients in whom severe sepsis/septic shock is suspected to facilitate the earliest recognition of this condition.

The usual bacteria cultured from urinary sources are aerobic Gram-negative bacilli and enterococci. If patients present with SIRS or sepsis, preoperative cultures should be reassessed to possibly redirect antibiotic therapy. These patients should be recultured with two sets of blood cultures and urine cultures from each drainage tube (including urethral and/or nephrostomy if present). If results are not available, empiric broad-spectrum antibiotics should be initiated as soon as possible to cover the most likely pathogens. Suggested primary regimens include the usage of ampicillin/gentamicin, piperacillin–tazobactam, or carbapenems (doripenem, imipenem, or meropenem); the duration of treatment is determined by the patient's clinical response. It is imperative to modify the antibiotic regimen to a culture directed one as soon as possible.

If severe sepsis/septic shock is recognized, besides empiric antibiotic therapy, prompt treatment in the intensive care unit should include repletion of intravascular volume with large amounts of crystalloid intravenous fluids. If necessary, vasopressors can be administered to maintain blood pressure and ensure adequate tissue perfusion. A central venous catheter can be placed and central venous pressures monitored for goal-directed fluid resuscitation although a Cochrane review demonstrated that invasive pressure monitoring did not change overall mortality rates [85]. Bicarbonate and low-dose steroids may be used and tight blood glucose control maintained. Tight blood glucose control by administration of insulin doses up to 50 U/hour is associated with a reduction in mortality. Multidisciplinary treatment is essential to obtain good results [7, 10, 86].

## Conclusions

Septic complications in genitourinary surgery are a life-threatening scenario that urologists wish to avoid during their practice. To achieve this goal or to minimize the risk of sepsis, a thorough medical history must be performed to identify patient risk factors; it is necessary to assess the appropriate time to perform surgery according to the potential infectious sources and to provide correct preoperative prophylaxis and follow-up. Once an infectious complication is suspected, it is imperative to act fast and accurately in a multidisciplinary fashion to avoid the progression of the natural history of sepsis and to provide a better opportunity for recovery.

## Introduction

In the early part of the twentieth century, infectious diseases were the most common causes of death across the globe. Technological advances such as improved sanitation and decreased pollution led to dramatic changes such that by the end of the twentieth century chronic, noncommunicable diseases accounted for the greatest number of deaths [1, 2]. Greater longevity can also be attributed to many of these changes. Diminished smoking, declining homicide rates, improved emergency and trauma care, and declining cancer rates have all contributed to the declining mortality rates. As living standards improved, life expectancy continued to increase such that the average life expectancy at birth was 71.4 years for the global population in 2015 [3].

In the United States, the top four causes of death can be attributed to chronic, age-related conditions such as heart disease, cancer, chronic respiratory diseases, and stroke [4, 5]. With an aging population and increasing prevalence of chronic diseases comes an ever increasing burden of complex comorbidities that challenge the physicians managing them with other more acute concurrent illnesses [4, 5]. IMS Health, a market research firm, released global sales data for the most prescribed drugs of 2015. Anticoagulants ranked 11th of the top 20 global therapy areas for pharmaceuticals. Out of top 20 prescribed drugs globally, Xarelto (rivaroxaban), an anticoagulant, was ranked 17th [6].

The increasing prevalence of chronic diseases, especially cardiovascular diseases, translates into increasing use of anticoagulants and antiplatelets and the so-called novel oral anticoagulants (NOACs) in clinical practice. It is not uncommon for surgeons to encounter patients using these agents who need surgical care. Intimate knowledge and mastery of the issues concerning their management in the perioperative setting is imperative. This chapter will articulate the pharmacological mechanisms of action, the indications and clinical applications, and the appropriate interval for interruption and bridging perioperatively. The risks of perioperative bleeding balanced against the risk of thromboembolic events will also be discussed.

## Challenges

It is estimated that there are over 6 million patients in the United States on anticoagulation medication for prevention of thromboembolism, and an ever-increasing number of patients are on dual antiplatelet therapy; 10% of these patients are purported to undergo surgery annually [7, 8]. Discontinuing anitcoagulants or antiplatelets is not without risk. Valve thrombosis carries a 10–20% mortality risk associated with emergency valve replacements. Coronary stent thrombosis carries a greater than 50% mortality in association with a myocardial infarction [9]. Compounding the issues further, hemorrhagic events carry a 9–13% mortality rate; however, long-term permanent disability is rare [5, 10]. For patients who experience a stroke, 20% are fatal while another 50% result in permanent neurological deficit [5]. The goal is balancing the risks of increased bleeding associated with surgery on anticoagulation while minimizing the risk of thromboembolic events.

## Anticoagulants and mechanisms of action

### Heparin

#### Unfractionated heparin

Heparin is supplied in two general formulations. Unfractionated heparin is a heterogenous mixture of

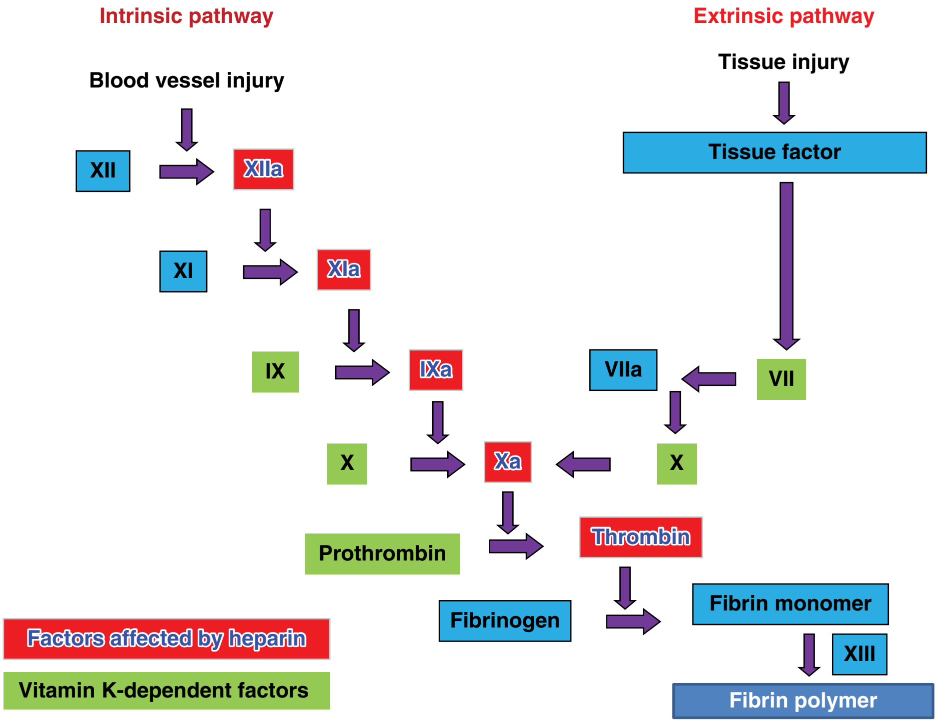

**Figure 5.1** Coagulation cascade.

glycosaminoglycans with varying molecular weights from 3000 to 30 000 Da with a mean of 15 000 Da, one-third of which will be biologically active. Heparin acts by binding to antithrombin and facilitating rapid inactivation of thrombin and factor Xa (Figure 5.1). The complexing of antithrombin and thrombin dissociates heparin and returns it to the circulation. Heparin also acts to inhibit platelet aggregation by its action on inhibition of thrombin [11, 12].

#### Low molecular weight heparin

Low molecular weight heparins (LMWH) are produced from unfractionated heparin by either chemical or enzymatic depolymerization. They have a molecular weight of 2000–10 000 Daltons with a mean of 4000–6500 Daltons. They are composed of mainly short-chain heparin molecules. They are unable to bridge antithrombin and thrombin, and mediate their effects mainly by the inhibition of factor Xa [11, 12].

#### Mechanism of action

Antithrombin has a low level of activity at baseline, mediated by an arginine center that binds to active serine proteases of the coagulation cascade. The bindings of heparin to antithrombin facilitates it inactivation of thrombin and factor Xa. The binding is specific and reversible and does not inactivate heparin. Once antithrombin is complexed with thrombin, the heparin molecule dissociates and returns to the circulation. Heparin also impairs platelet aggregation by directly binding to platelets. The high molecular weight heparins are the molecules thought to be most active in this mechanism. Reversal of heparin is accomplished by withholding the drug. For emergent cases or when supratherapeutic, protamine sulfate is used as a reversal agent [11, 12].

### Warfarin

Warfarin is the most commonly used vitamin K antagonist. It acts via the intrinsic pathway by inhibition of factors II, VII, IX, and X, and proteins C, S, and Z (Figure 5.1). Warfarin is available as an intravenous preparation, but is most administered orally, is water soluble, and rapidly absorbed. It has high bioavailability and reaches maximal serum concentration within 90 minutes of administration. It has a half-life of 36–42 hours. It circulates bound to albumin and other plasma proteins and is eliminated by the liver. Therefore, its activity is highly influenced by drug–drug interactions, diet (particularly foods rich in vitamin K), comorbidities, genetic variability, and diet. After initial administration, there is a period of hypercoagulability as a result of the transient reduction of vitamin K-dependent anticoagulant proteins. Hence, initiation of warfarin therapy is often accompanied by a period of concomitant heparinization with unfractionated or LMWH. The full anticoagulation effect of warfarin may not be seen for 6 days. Frequent prothrombin time and international normalized ratio (PT/INR) monitoring is done until full therapeutic dose is achieved. Warfarin is indicated for the treatment of atrial fibrillation, atrial flutter, venous thromboembolism (VTE) prophylaxis, deep venous thrombosis (DVT), pulmonary embolism, hypercoagulable states, and valvular disease [11, 12]. Reversal of the effect of warfarin is accomplished by withholding the medication. The PT/INR will slowly normalize over a period of 5 days. More rapid reversal can be achieved by oral administration of low-dose vitamin K (2–2.5 mg) as recommended by the guidelines of the American College of Chest Physicians (ACCP) [8]. Administration of fresh frozen plasma may be required also.

## Dabigatran

Dabigatran etexilate is an oral direct factor IIA (thrombin) inhibitor (Figure 5.1). Once ingested, dabigatran etexilate is converted to its active form, dabigatran, a potent, competitive, and reversible direct inhibitor that binds to the active site on thrombin, thereby inactivating both fibrin-bound and unbound thrombin. Plasma levels reach a peak at 1.25–3 hours after ingestion. Therapeutic effect is achieved 2–3 hours after ingestion and it has a half-life of 12–14 hours. Excretion is predominantly renal; therefore, dosing is adjusted according to creatinine clearance. It is not recommended in patients with a creatinine clearance of <15 ml/minute. Discontinuation of dabigatran should be done 24–48 hours before surgery, and preferably 5 days ahead for cases where severe risk of bleeding is expected. Reversal of the action of dabigatran is possible with a newly approved monoclonal antibody antidote, idarucizumab (Praxbind), which directly targets dabigatran and can reverse the anticoagulant effects of dabigatran within minutes of administration [11, 12].

## Rivaroxaban

Rivaroxaban is an oral selective inhibitor of factor Xa. It targets both free factor Xa and bound factor Xa in the prothrombinase complex (Figure 5.1). The half-life of rivaroxaban is 11–13 hours and reaches peak plasma concentration 2–4 hours after oral administration. As with dabigatran, bridging with heparin is not needed when discontinued or restarted after interruption. It is approved for stroke prevention in patients with nonvalvular atrial fibrillation. Clinical indications have been expanded to include treatment of DVT and VTE events, prevention of DVT, and pulmonary embolism after hip or knee arthroplasty. Cessation prior to surgery is recommended 24–48 hours before surgery and resumption 6–10 hours after surgery, or when hemostasis is deemed adequate or the risk of severe hemorrhage has diminished [11, 12].

## Apixaban

Apixaban is another oral selective direct inhibitor of free and clot-bound factor Xa (Figure 5.1). After oral administration, peak plasma concentrations are achieved within 1–4 hours. It is predominantly metabolized by the liver and has several important drug interaction cautions against concomitant usage with drugs affecting CYP3A4. It has no antiplatelet activity. It is currently approved for the prevention of stroke and thromboembolic events in patients with nonvalvular atrial fibrillation. It is used for prophylaxis against DVT and pulmonary embolism after recent knee or hip replacement, and treatment of DVT and pulmonary embolism, and there is a reduction in risk of recurrence following initial therapy [11, 12].

## Edoxaban

Edoxaban is another oral anticoagulant drug which acts as a reversible, direct factor Xa inhibitor, that binds to blocks the active site of factor Xa. It inhibits free factor Xa and prothrombinase complex activity and inhibits thrombin-induced platelet aggregation (Figure 5.1). Primarily, it is excreted as unchanged drug in urine; metabolism and biliary/intestinal excretion account for the remainder of its clearance. Peak plasma concentration is achieved within 1–2 hours of oral administration. The half life of edoxaban is 10–14 hours, achieving total clearance in about 22 hours. Therefore, cessation is advised at least 24 hours prior to invasive or surgical intervention. Parenteral anticoagulant administration is advised prior to initiation of edoxaban. Edoxaban is approved for the treatment of DVT and pulmonary embolism, prevention of stroke, and systemic embolism in patients with nonvalvular atrial fibrillation [11–13].

## Clopidogrel

Clopidogrel is a prodrug which upon activation by CY2C19 acts by irreversibly inhibiting the P2Y12 subtype of the adenosine diphosphate (ADP) receptor on platelet cell membranes. The P2Y12 subtype of the ADP receptor is important in activation of platelets and eventual crosslinking by the protein fibrin. Platelet inhibition can be seen 2 hours after oral administration of a single dose. However, the onset of action is slow, hence a loading dose is recommended if rapid effect is needed. The elimination half-life of clopidogrel is 0.5–1.0 h. Some 50% was excreted in the urine and 46% in the feces in the

5 days after dosing. It inhibits aggregation for the life of the platelet, typically 7–10 days. Bleeding time and platelet function return to baseline after 5 days. Cessation is recommended 7–10 days prior to any planned surgery [11, 12].

### Ticlopidine

Ticlopidine is another oral thienopyridine, similar in action and mechanism to clopidogrel. It exhibits high bioavailability up to 80% with rapid absorption. The drug is metabolized into its active form which irreversibly blocks the ADP receptor on the surface of platelets. Antiplatelet effect is demonstrated within 2 days of initiation of therapy and reaches maximum effect after 6 days. The drug is metabolized by the liver, with elimination via renal and fecal routes. After the first dose the half life is 12.6 hours, but this is prolonged to 4–5 days with repeated dosing. The effects persist for 3 days after discontinuing ticlopidine although it may take 1–2 weeks for platelet function to return to normalize [11, 12].

### Prasugrel

Prasugrel is yet another oral thienopyridine class of ADP receptor inhibitors, Similar in mechanism and action to clopidorgel and ticlopidine, it acts by irreversible binding to P2Y12 receptors in platelets and thus prevents platelet aggregation. Prasugrel is a prodrug that is rapidly metabolized by esterases in the intestine and blood serum to an inactive thiolactone, which is then further converted to a pharmacologically active metabolite via CYP450-mediated oxidation, primarily CYP3A4 and CYP2B6. It has an elimination half-life of 2–15 hours. Antiplatelet activity is seen within 1 hour of oral administration. Maximal effect is seen after about 3–5 days of dosing at 10 mg daily following a loading dose of 60 mg. Platelet aggregation returns to baseline in 5–9 days after cessation of the drug. Since the inhibition is irreversible, the return to normal platelet function reflects the production of new platelets [11, 12].

### Ticagrelor

Ticagrelor blocks ADP receptors of subtype P2Y12. Its binding site is different from ADP and the binding is reversible. It does not rely on hepatic activation via the CYP2C19 enzyme; therefore, it is potentially more useful in patients with genetic variants of the enzyme. Ticagrelor, once administered orally, reaches its peak concentration after about 1.5 hours. The main metabolite is formed quickly via CYP3A4 and peaks after about 2.5 hours. Both ticagrelor and its metabolite are pharmacologically active. Excretion of the drug and its metabolite are mainly via bile and feces [11, 12].

## Safety of antithrombotics and risk stratification

The decision of whether or not to interrupt or hold anticoagulants and antiplatelets before surgery can sometimes be complex and prove to be a significant challenge for the surgeon. Interrupting or reversing anticoagulation therapy may lead to transient rebound hypercoagulability as a result of stopping and subsequently restarting anticoagulation therapy. Therefore, the risk of cessation needs stratification and to be weighed against the risk of bleeding from the surgery if the patient is to remain on anticoagulation throughout. The indication for anticoagulation therapy and the length of therapy must be evaluated. Before coming to a decision on interruption and resumption of anticoagulation, the indications for surgery need to be considered, alternatives to surgery and other surgical options assessed, and the associated bleeding risks evaluated. The underlying disease requiring the anticoagulation and coexisting cardiovascular diseases need to be considered in conjunction with the risk of thrombosis.

## Atrial fibrillation, risk of thromboembolism, and bleeding risk

The most commonly used method to predict thromboembolic risk in atrial fibrillation is the CHA2DS2-VASc score. It was developed by the American College of Cardiology (ACC) in conjunction with the American Heart Association and European Society of Cardiology. The acronym stands for Congestive heart failure, Hypertension, Age >75 (2 points), Diabetes, and Stroke or transient ischemic attack (TIA) or thromboembolism (2 points), and VASc stands for Vascular disease (peripheral arterial disease, previous myocardial infarction, aortic plaque), Age 65–74 (1 point), and Sex category (female gender 1 point). It allows for an individualized approach to the prediction and the selection of antithrombotic agents for the prevention on the basis of patient risk for stroke and risk for intracranial hemorrhage. Each risk factor receives 1 point except age > 75 and stroke/TIA which receive 2 points. The more points on the CHA2DS2-VASc score, the higher the annual stroke risk in general [14–16]. Other predisposing factors such as the presence of mechanical heart valves, underlying diseases causing a hypercoagulable state, renal impairment, cardiomyopathy, atrial thrombus, and concurrent malignancy should also be considered when evaluating the risk of thromboembolism.

## Bleeding risk

Several tools have been proposed and used for the assessment of bleeding risk in atrial fibrillation patients on anticoagulation. The HAS-BLED score represents the most recent tool for this purpose and stands for Hypertension (uncontrolled systolic blood pressure >160 mmHg), Abnormal renal or liver function, Stroke, Bleeding history, Labile international normalized ratios, Elderly, and concomitant Drugs and/or alcohol excess [17]. Each risk factor assigns 1 point and scores range from 0 to 9. Scores of ≥3 indicate a high risk of bleeding at 1 year. For these patients, caution with anticoagulation use is recommended. The HAS-BLED score can be a guide for surgeons in the evaluation of bleeding risk in atrial fibrillation patients.

## Pulmonary embolism and deep venous thromboembolic disease

Patients suffering from pulmonary embolism are particularly challenging to manage. The risk of a recurrent thromboembolic event can be immediately catastrophic. Not unlike atrial fibrillation, the length of therapy is important when considering cessation or interruptions in anticoagulants. The risk of recurrence with temporary cessation is lowest in patients who have been treated for at least 1 month, and preferably longer. For those patients who have been treated for less than 1 month, alternatives to surgery and, if possible, delaying surgery should be considered. If emergent or urgent surgery is indicated, then these patients need to be bridged as the risk of recurrence or propagation is highest in this group [18, 19].

## Mechanical heart valves

Patients with mechanical heart valves an especially complex group since they all need to remain anticoagulated. Common types of heart valve prostheses include the St Jude's Medical bileaflet valve, the Starr–Edwards ball-and-cage design, the Bjork–Shiley tilting disc design, and the stented porcine prosthesis. The type and position of the heart valve needs to be considered as they influence risk of thrombosis. Thromboembolism risk is higher with the Starr–Edwards ball-and-cage design than with the Bjork–Shiley tilting disc. Bileaflet prosthetic valves such as the St Jude valve have the lowest risk of thromboembolism. Mitral valve replacement carries the higher rates of thromboembolism compared to aortic valve replacement. Patients with any mitral valve replacement or a mechanical aortic valve replacement requiring anticoagulation will need to be bridged with unfractionated heparin which can then be held 1–4 hours before the surgery [20].

## Hypercoagulable states

The risk of thromboembolism is particularly vexing in patients with inherited and acquired thrombophilia. They often require special preparation due to the increased risk of thrombosis associated with interrupting and resuming anticoagulation. These patients should be considered at high risk for adverse for interrupting anticoagulation. Careful preparation and individualized approach to bridging and management in conjunction with a hematologist, to minimize the risk.

## Coronary stents

Bare metal stents (BMS) and drug-eluting stents (DES) are designed to combat the problem of acute reocclusion or re-stenosis after percutaneous coronary balloon angioplasty. Both types of stents reduce the risk of reocclusion and re-stenosis. It has been stated that up to 30% of patients with BMS develop re-stenosis within the first year due to intimal hyperplasia. DES, which have a polymer coating that binds antiproliferative drugs such as sirolimus, paclitaxel, or everolimus to the stent and releases the drug, reduces risk of stent re-stenosis by up to 70% [9, 21, 22]. However, due to this same mechanism, the length of time to complete endothelialization of the stent is prolonged in DES, thus increasing the risk of acute stent thrombosis. Thus prolonged antiplatelet therapy is required in DES, compared to BMS. The ACC recommends dual antiplatelet therapy for at least 14 days after balloon angioplasty, 1 month for BMS, and 6–12 months for DES. Coupled with the increasing use of intracoronary stents there is an increasing incidence of these patients presenting for noncardiac surgeries while still within the mandatory time recommended for antiplatelet therapy. The risks of significant hemorrhage and ischemia under these circumstances is not insignificant and pose a particular challenge for the surgeon. For certain subgroups of these patients who have severe coronary disease and carry the greatest risk of a major adverse cardiac event, the cardiologist may insist on life-long antiplatelet therapy. The ACC guidelines recommend delaying surgery if the period of dual antiplatelet therapy is less than 1 month for BMS or less than 3 months for DES. For patients with DES, if surgery is within 3–6 months of initiation of dual antiplatelet therapy after percutaneous coronary intervention, then the risk of delaying surgery should be weighed against the risk of stent thrombosis [23].

## Risk of thrombosis

The 2012 guidelines of the ACCP stratify patients into the following thrombotic risk categories (see

**Table 5.1** Summary of ACCP 2012 Guidelines for risk categorization and perioperative bridging.

| Risk category | Atrial fibrillation | Mechanical heart valve | VTE |
|---|---|---|---|
| High (must bridge; >10% annual risk of thromboembolism) | CHADS2 of 5 or 6 | Any mitral valve prosthesis | Recent VTE (within 3 months) |
| | Recent stroke or TIA within 3 months | Any caged ball or tilting disc aortic valve prosthesis | Severe thrombophilia<br>• Protein C, protein S, or antithrombin deficiency<br>• Antiphospholipid antibodies<br>• Multiple abnormalities |
| | Rheumatic valvular heart disease | Recent stroke or TIA (within 6 months) | |
| Moderate (consider bridging based on patient and surgery-specific factors; 5–10% annual risk of thromboembolism) | CHADS2 of 3 or 4 | Bileaflet aortic valve prosthesis and one or more risk factors:<br>• Atrial fibrillation<br>• Prior stroke or TIA<br>• Hypertension<br>• Diabetes<br>• Congestive heart failure<br>• Age >75 years | VTE within the past 3–12 months<br>Non-severe thrombophilia:<br>• Heterozygous factor V Leiden<br>• Prothrombin gene mutation |
| | | | Recurrent VTE |
| | | | Active cancer (treated within 6 months or palliative) |
| | | | VTE >12 months and no other risk factors |
| Low (no bridging needed; <5% annual risk of thromboembolism) | CHADS2 of 0–2 and no prior stroke or TIA | Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke | |

Table 5.1): low risk (less than 5% risk of thrombotic events per year), moderate risk (5–10% risk of thrombotic events per year), and high risk (greater than 10% risk of thrombotic events per year) [8]. According to the panel, patient at high risk should undergo bridging, patients at moderate risk should be considered for bridging, while patients at low risk do not need to be bridged [8].

## Perioperative management of patients receiving vitamin K antagonist (warfarin) therapy

### Interruption and resumption before surgery

For patients who require temporary interruption of warfarin before surgery, the panel recommends stopping warfarin approximately 5 days before surgery. For patients requiring temporary interruption of warfarin before surgery, resuming warfarin is recommended approximately 12–24 h after surgery and when there is adequate hemostasis [8, 23].

### Need for bridging anticoagulation during interruption of therapy

For those patients with mechanical heart valves, atrial fibrillation, or VTE who are considered at high risk for thromboembolism, the panel suggests bridging anticoagulation when interrupting warfarin therapy. In patients with a mechanical heart valve, atrial fibrillation, or VTE at moderate risk for thromboembolism, the decision to bridge or not to bridge is based on an assessment of the individual patient and surgery-related factors. For patients with mechanical heart valves, atrial fibrillation, or VTE considered to be at low risk for thromboembolism, the panel does not recommend bridging anticoagulation when interrupting warfarin therapy (Table 5.1) [8, 23].

### Perioperative management for patients who require minor procedures

When the surgery is considered to be minor and carrying a low risk of hemorrhage, the panel suggests continuing warfarin with concomitant oral prohemostatic agent or interrupting warfarin 2–3 days before the procedure, optimizing local hemostasis [8, 23].

## Perioperative management of patients who are receiving antiplatelet drugs

### Non-cardiac surgery and aspirin

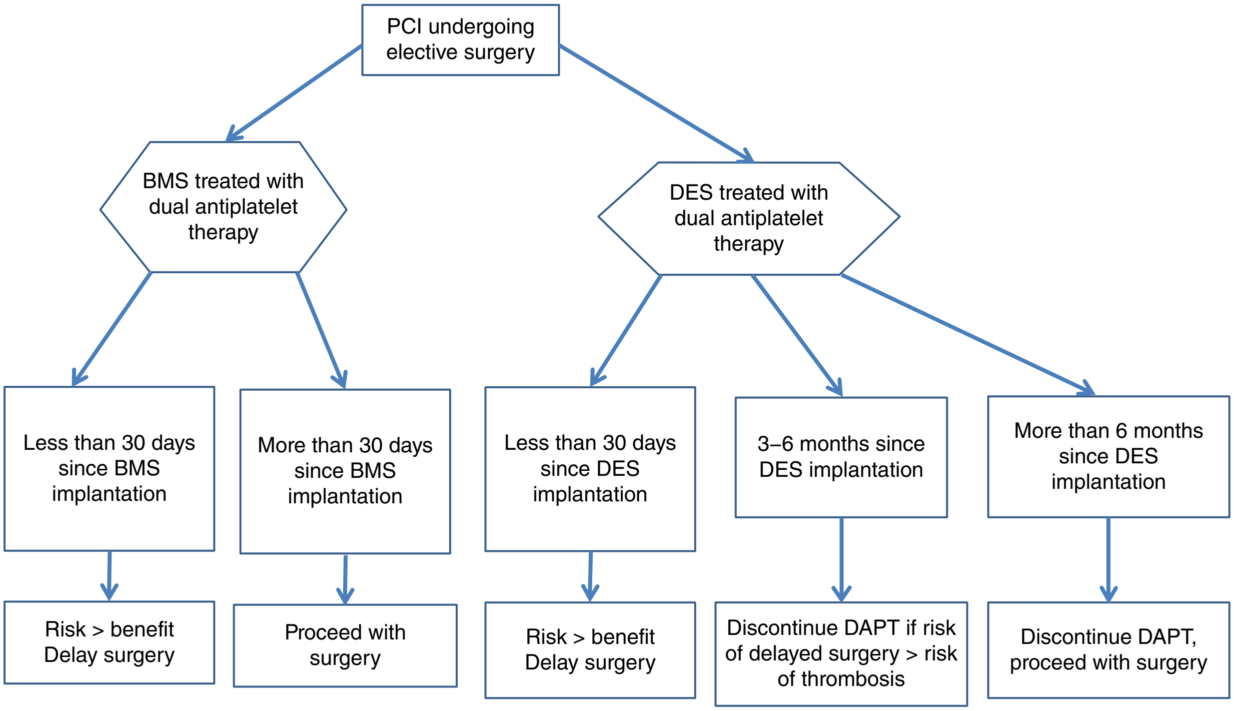
In patients considered to be at moderate to high risk for cardiovascular events who are on aspirin and require noncardiac surgery, the panel recommends continuing aspirin around the time of surgery instead of stopping aspirin 7–10 days before surgery. In patients at low risk for cardiovascular events who are receiving aspirin therapy, the panel suggest stopping aspirin 7–10 days before surgery instead of continuation [8, 23].

### Patients with coronary stents having surgery

Patients with a coronary stent who are receiving dual antiplatelet therapy and require surgery, the panel recommends deferring surgery for at least 6 weeks after placement of a BMS and for at least 6 months after placement of a DES instead of undertaking surgery within these time periods (Figure 5.2). In patients who require surgery within 6 weeks of placement of a BMS or within 6 months of placement of a DES, the panel suggests continuing dual antiplatelet therapy around the time of surgery instead of discontinuing dual antiplatelet therapy 7–10 days before surgery. One should note that the most recent guidelines from the ACC, published in 2016, shortened the mandatory time period during which surgery must be delayed to 1 month after placement of BMS and 3 months for DES before interruptions of dual antiplatelet therapy can be considered [23]. This is discussed elsewhere in this chapter in the section on coronary stents [8, 23].

## Perioperative use of bridging intravenous unfractionated heparin and LMWH

In patients who are receiving bridging anticoagulation with therapeutic-dose unfractionated heparin, the panel suggests stopping unfractionated heparin 4–6 hours before surgery. For those patients who are being bridged with therapeutic-dose subcutaneous LMWH, the panel recommends administering the last preoperative dose approximately 24 hours before surgery. For those patients being bridged with therapeutic doses of subcutaneous LMWH and are undergoing surgeries with high risk for hemorrhage, the panel recommends resuming



PCI undergoing elective surgery
BMS treated with dual antiplatelet therapy
DES treated with dual antiplatelet therapy
Less than 30 days since BMS implantation
More than 30 days since BMS implantation
Less than 30 days since DES implantation
3–6 months since DES implantation
More than 6 months since DES implantation
Risk > benefit Delay surgery
Proceed with surgery
Risk > benefit Delay surgery
Discontinue DAPT if risk of delayed surgery > risk of thrombosis
Discontinue DAPT, proceed with surgery

**Figure 5.2** 2016 ACC/American Heart Association treatment algorithm for timing of elective noncardiac surgery in patients with coronary stents [23]. DAPT, dual antiplatelet therapy; PCI, percutaneous coronary intervention.

therapeutic-dose LMWH 48–72 hours after surgery instead of resuming LMWH within 24 hours after surgery. If the surgery poses a low risk of significant hemorrhage, resuming therapeutic-dose LMWH approximately 24 hours after surgery is recommended [8, 23].

## Antiplatelet and anticoagulant use in urological surgery

There is very limited evidence-based literature on the perioperative management of patients who are scheduled for urological surgery. In deciding on a management scheme for interrupting and resuming antiplatelets and anticoagulation during elective urological surgery, certain patient and procedural risk factors need to be considered. The risk of thromboembolic event or stent stenosis needs to be considered along with comorbid conditions. Patients with severe coronary artery disease with multiple stents, stent re-stenosis, poor ejection fraction, and renal failure need to be weighed against the risk of bleeding or significant hemorrhage associated with the planned surgery. Consultation and comanagement with the patient's cardiologist and hematologist, as well as the anesthesiologist, is necessary to minimize the risk of adverse outcomes.

In Table 5.2 the most common types of urological surgery are categorized according to bleeding risk. Table 5.2 categorizes the patients into low-, moderate-, and high-risk groups according to the ACC and ACCP guidelines. For most cases, aspirin can be continued perioperatively in patients with intracoronary stenting, as prematurely interrupting aspirin is a risk factor for acute coronary syndrome and stent thrombosis. However, if the risk of bleeding is considered to be severe, aspirin should be interrupted for the surgery and then resumed as soon as the window for severe bleeding has elapsed. Several studies of perioperative aspirin and anticoagulation use during transurethral resection of the prostate have demonstrated an increased rate of postoperative bleeding, likewise for transurethral laser enucleation techniques [24–29]. However, for transurethral vaporization techniques, there does not appear to be a significantly increased risk of bleeding for patients receiving clopidogrel, aspirin, or warfarin compared to controls [24–29]. Pregnancy and uncorrected coagulopathy are the two absolute contraindications for shock-wave lithotripsy. It can carry a high risk of hemorrhagic complications including postoperative perirenal hematomas and life-threatening renal hemorrhage, resulting in transfusion, renal embolization, and nephrectomy. The rate of asymptomatic perirenal hematomas can be as high as 25% when sensitive abdominal computed tomography scanning is used postoperatively, and rate of symptomatic hematomas have been reported to be 0.7% [30–32]. Patients that cannot discontinue anticoagulants and antiplatelets are usually managed with other modalities [33–36]. Several series have reported results of the use of the anticoagulants and antiplatelets in conjunction with shock-wave lithotripsy, some with catastrophic outcomes [37]. In patients undergoing transrectal ultrasound-guided prostate biopsy (TRUS Bx) there is an increased the risk of prolongation of rectal bleeding, hematuria, and hematospermia in association with antiplatelets and anticoagulants use [29, 38–40]. A prospective randomized trial published in 2007 found that the median duration of hematuria and rectal bleeding was statistically significantly greater in uninterrupted aspirin use (group 1) and interrupted but bridged with LMWH (group 2) compared to interrupted aspirin (group 3): 6, 4, and 2 days and 3, 2, and 1 days, respectively. The number of patients still reporting hematospermia at 30 days after TRUS Bx was 21.4, 18.5, and 9.3% in groups 1, 2, and 3, respectively [38].

Ureteroscopy is considered safe in the face of anticoagulation and antiplatelets. Turna et al. published a retrospective case-control study of flexible ureteroscopy and holium:YAG laser lithotripsy [41]. They identified 37 patients on warfarin (38%), clopidogrel (13%), or aspirin (49%) who underwent surgery without interruption of antithrombotic therapy. There were no bleeding-related complications in either group [41].

**Table 5.2** Bleeding risk categories for common urological surgeries.

| Low risk | Moderate risk | High risk |
|---|---|---|
| Cystoscopy | Laser enucleation of prostate | Cystectomy |
| Ureteroscopy/renoscopy | Transurethral resection of prostate | Partial and total nephrectomy |
| Laser lithotripsy | Transurethral resection of bladder | Prostatectomy |
| Laser vaporization of prostate | Transrectal biopsy of prostate | Penile prosthesis |
| Urethral bulking | Urethral sling and sphincter placements | Penectomy |
| | Prolapse repair | Shockwave lithotripsy |

Several series have also been published on use of aspiring during other high-risk procedures [42, 43]. Leyh-Bannurah et al. reported on a retrospective series of 137 open retropubic and robot-assisted radical prostatectomy (RARP) in patients on uninterrupted aspirin therapy compared to controls matched by propensity score. The authors did not observe a statistically significant increase in blood loss in the aspirin group. However, they did observe that aspirin was an independent predictor of blood transfusion [42]. Likewise for robot-assisted laparoscopic radical nephrectomy (RALRN) and RALRP, Parikh et al. reported on 51 patients who underwent RARP while continuing aspirin compared to 44 controls. There was no significant difference in estimated blood loss, and there were no transfusions in either group. Results were similar for the RALRN group which had 14 patients with uninterrupted aspirin versus 12 controls [44].

In contrast to aspirin, clopidogrel, cilostazol, and warfarin were associated with an increased risk of thrombotic events postoperatively in patients undergoing open or laparoscopic partial nephrectomy in a retrospective series of 47 chronically anticoagulated patients who had the anticoagulation interrupted [45]. In that series, the transfusion rates were similar to the matched control group. Similar findings were observed in patients with a percutaneous nephrolithotomy [46]. However, a recent series of uninterrupted aspirin therapy in patients undergoing percutaneous nephrolithotomy did not show an difference in bleeding complications compared to controls [47].

## Conclusion

With the increasing prevalence of patients with coronary stents and who are on antiplatelet therapy or anticoagulation, urologists are increasingly more likely to be needed to perform surgeries. Sometimes the underlying indication for surgery can be life threatening, creating an incredibly complex set of difficult medical choices. Taken together, the evidence base upon which to draw conclusions and guide management is sparse and of suboptimal quality. It thus becomes imperative to categorize the patient's risk group and to balance the risk of hemorrhagic consequences with the risk of thromboembolic events. A multidisciplinary approach is essential for optimal management of these patients.

## Surgical Anatomy of the Kidney for Endourological Procedures

*Francisco J.B. Sampaio*

*Urogenital Research Unit, State University of Rio de Janeiro, Rio de Janeiro, Brazil*

## General anatomy

The kidneys are paired organs lying retroperitoneally on the posterior abdominal wall. Each kidney has a characteristic shape, with a superior and an inferior pole, a convex border placed laterally, and a concave medial border. The medial border has a marked depression, the hilum, containing the renal vessels and renal pelvis.

### Renal morphometry

In adults, the left kidney is larger than the right, and this agrees with morphometric findings in fetal kidneys [1]. The right kidney has a mean length of 10.97 cm and 3.21 cm mean thickness at the hilum, in comparison to 11.21 cm and 3.37 cm, respectively, for the left kidney [2].

An interesting finding is that the superior pole has a greater width (mean, 6.48 cm) than the inferior pole (mean, 5.39 cm). Also, there is a statistically significant correlation between kidney length and an individual's stature [2].

### Position of the kidneys

Because the kidneys lie on the posterior abdominal wall, against the psoas major muscles, their longitudinal axis parallels the oblique course of the psoas (Figure 6.1). Moreover, since the psoas major muscle has a cone shape, the kidneys also are dorsally inclined on the longitudinal axis. Therefore, the superior poles are more medial and more posterior than the inferior poles (Figure 6.1). Also, because the hilar region is rotated anteriorly on the psoas muscle, the lateral borders of both kidneys are posteriorly positioned. This means the kidneys are angled 30–50° behind the frontal (coronal) plane (Figure 6.2) [3].

### Perirenal coverings

The kidney surface is enclosed in a continuous covering of fibrous tissue, the renal capsule ("true renal capsule"). Each kidney within its capsule is surrounded by a mass of adipose tissue, lying between the peritoneum and the posterior abdominal wall (Figures 6.2 and 6.3). This perirenal fat is enclosed by the renal fascia (the so-called fibrous renal fascia of Gerota). The renal fascia is enclosed anteriorly and posteriorly by another layer of adipose tissue, the pararenal fat, which varies in thickness (Figure 6.3).

The renal fascia is made up of a posterior layer (a well-defined and strong structure) and an anterior layer (a more delicate structure, which tends to adhere to the peritoneum) (Figures 6.2 and 6.3). The anterior and posterior layers of the renal fascia (fascia of Gerota) subdivide the retroperitoneal space into three potential compartments: (i) the posterior pararenal space, which contains only fat; (ii) the intermediate perirenal space, which contains the suprarenal glands, kidneys, and proximal ureters, together with the perirenal fat; and (iii) the anterior pararenal space, which unlike the posterior and intermediate spaces, extends across the midline from one side of the abdomen to the other. This latter space contains the ascending and descending colon, the duodenal loop, and the pancreas [3] (Figure 6.4). Inferiorly, the layers of the renal fascia end weakly fused around the ureter (Figures 6.3 and 6.5). Superiorly, the two layers of the renal fascia fuse above the suprarenal gland and end fused with the infradiaphragmatic fascia (Figure 6.5). An additional fascial layer separates the suprarenal gland from the kidney (Figure 6.5). Laterally, the two layers of the renal fascia fuse behind the ascending and descending colons. Medially, the posterior fascial layer is fused with the fascia of the spine muscles. The anterior fascial layer merges into the connective tissue of the great vessels (aorta and inferior vena cava) (Figures 6.2 and 6.4).

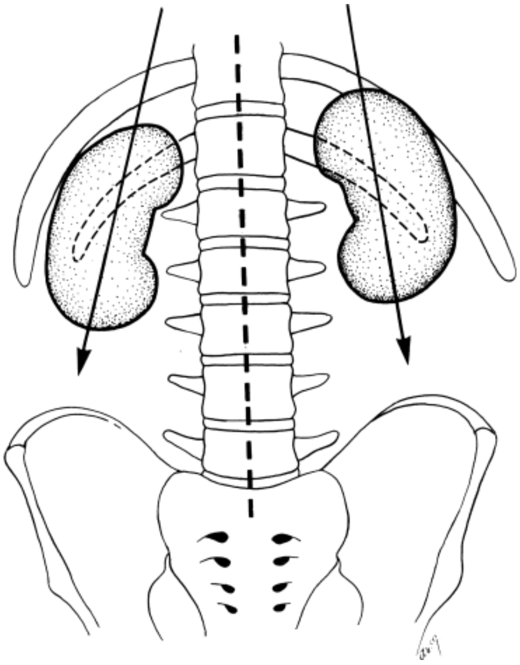

Figure 6.1 Schematic of an anterior view of the kidneys in relation to the skeleton showing that the longitudinal axes of the kidneys are oblique (arrows), with the superior poles more medial than the inferior poles. The dashed lines mark the longitudinal axis of the body. It can also be seen that usually the posterior surface of the right kidney is crossed by the 12th rib and the left kidney by the 11th and 12th ribs.

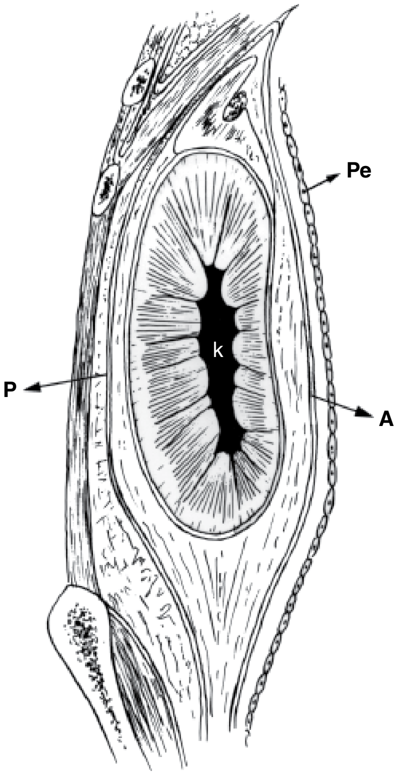

Figure 6.3 Schematic of a lateral view of a longitudinal section through the retroperitoneum showing the posterior (P) and anterior (A) layers of the renal fascia. Pe, peritoneum; k, kidney.

These anatomic descriptions of the renal fascia show that the right and left perirenal spaces are potentially separated and, therefore, it is exceptional that a complication of an endourologic procedure, e.g. hematoma, urinoma, or perirenal abscess, involves the contralateral perirenal space [3].

## Relationship of kidneys to the diaphragm, ribs, and pleura

The kidneys lie on the psoas and quadratus lumborum muscles. Usually, the left kidney is higher than the right kidney, with the posterior surface of the right kidney crossed by the 12th rib and the left kidney crossed by the 11th and 12th ribs (Figure 6.1). The posterior surface of the diaphragm attaches to the extremities of the 11th and 12th ribs (Figure 6.6). Close to the spine, the diaphragm is attached over the posterior abdominal muscles, and forms the medial and lateral arcuate ligaments on each side (Figure 6.6). In this way, the posterior aspect of the diaphragm (posterior leaves) arches in a dome above the superior pole of the kidneys, on each side. Therefore, when performing an intrarenal access by puncture, the endourologist may consider that the diaphragm is traversed by all intercostal punctures, and possibly by some punctures below the 12th rib (Figure 6.7). Also, it can be

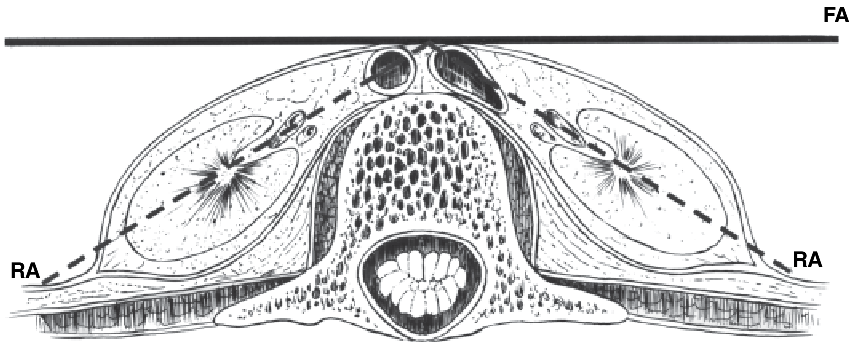

Figure 6.2 Schematic of a superior view of a transverse section of the kidneys at the level of the second lumbar vertebra showing that the kidneys are angled 30–50° behind the frontal (coronal) plane of the body (FA). RA, renal frontal (coronal) axis.

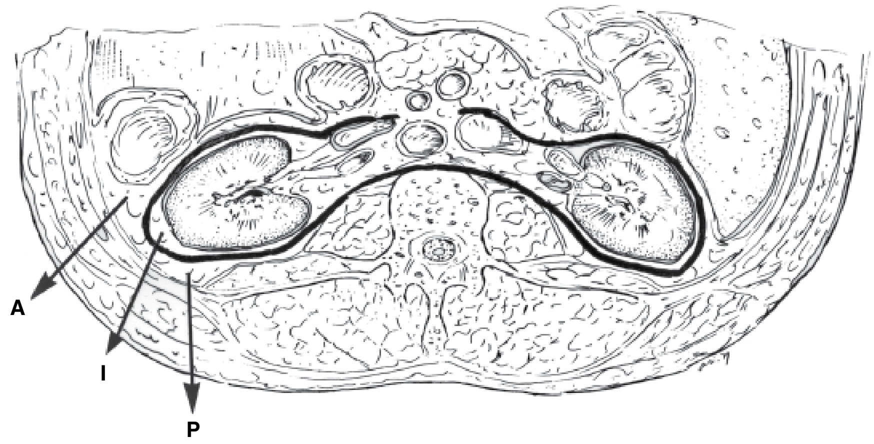

**Figure 6.4** Schematic of a superior view of a transverse section of the kidneys at the level of the second lumbar vertebra showing the three compartments of the retroperitoneal space. P, posterior pararenal space, which contains only fat; I, intermediate perirenal space, which contains the suprarenal glands, kidneys, and proximal ureters, together with the perirenal fat; and A, anterior pararenal space, which unlike the posterior and intermediate spaces, extends across the midline from one side of the abdomen to the other, and contains the ascending and descending colons, duodenal loop, and pancreas.

This shows that the two layers of the renal fascia fuse above the suprarenal gland and end fused with the infradiaphragmatic fascia (long arrow). Note a dependence of the fascia separating the suprarenal gland from the kidney (short arrow). D, diaphragm muscle.

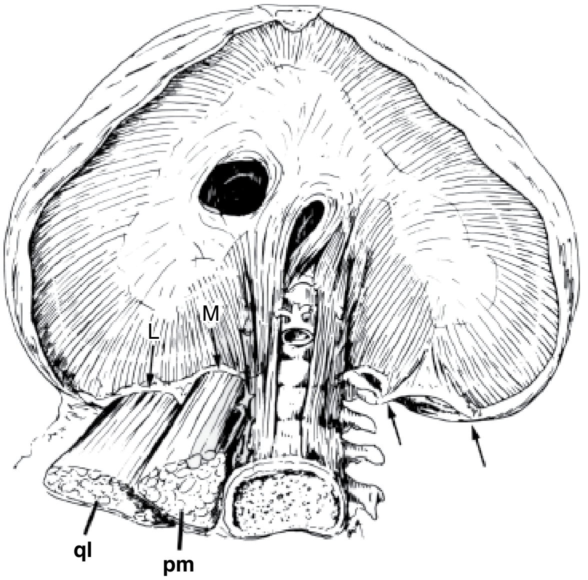

**Figure 6.6** Schematic of an inferior view of the diaphragmatic dome. The arrows point to the diaphragmatic attachments to the extremities of the 11th and 12th ribs. M, medial arcuate ligament; L, lateral arcuate ligament; ql, quadratus lumborum muscle; pm, psoas muscle.

expected that the pleura is transversed without symptoms in most intercostal approaches [4].

Generally, the posterior reflection of the pleura extends inferiorly to the 12th rib; nevertheless, the lowermost lung edge lies above the 11th rib (at the 10th intercostal space) (Figure 6.7). Regardless of the degree of respiration (mid or full expiration), the risk of injury to the lung from a 10th intercostal percutaneous approach to the kidney is prohibitive [4]. Any intercostal puncture should be made in the lower half of the intercostal space, in order to avoid injury to the intercostal vessels above.

## Relationship of kidneys to the liver and spleen

The liver on the right side and the spleen on the left may be posterolaterally positioned at the level of the suprahilar region of the kidney, because at this point these organs have their largest dimensions (Figure 6.8). Therefore, it should be remembered that a kidney puncture performed high in the abdomen will allow little space for the needle entrance [4]. If the intrarenal puncture is performed when the patient is in mid or full inspiration, the risk of injury to the liver and spleen is increased [4]. This knowledge is particularly important in patients with hepatomegaly or splenomegaly, in whom a computed tomography (CT) scan should be performed before puncturing the kidney.

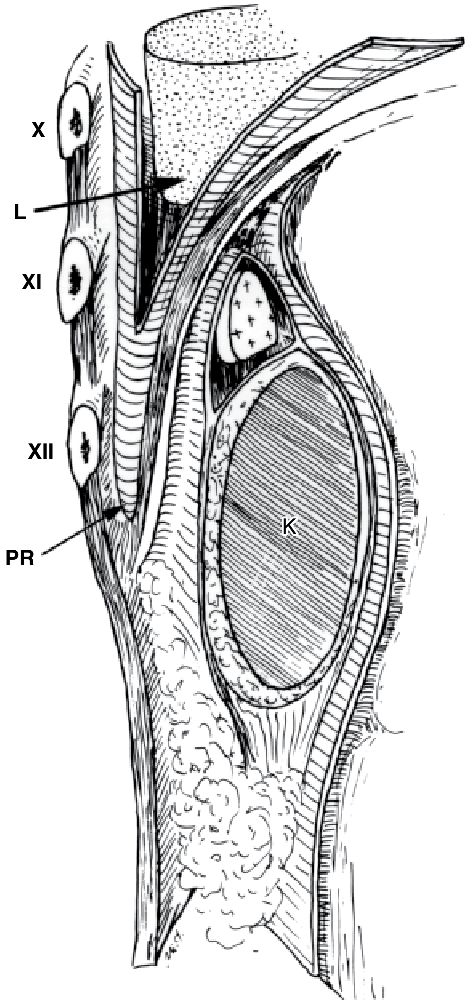

Figure 6.7 Schematic of a lateral view of the kidney and its relationships with the diaphragm, ribs, pleura, and lung. PR, posterior reflection of the pleura, L, lower edge of the lung; K, kidney; X, 10th rib; XI, 11th rib; XII, 12th rib.

## Relationship of kidneys to the ascending and descending colons

The ascending colon runs from the ileocolic valve to the right colic flexure (hepatic flexure), where it passes into the transverse colon. The hepatic colic flexure (hepatic angle) lies anteriorly to the inferior portion of the right kidney. The descending colon extends inferiorly from the left colic flexure (splenic flexure) to the level of the iliac crest. The left colic flexure lies anterolateral to the left kidney.

It is important to consider the position of the retroperitoneal ascending and descending colons. Occasionally, in the course of a routine abdominal CT scan, the retroperitoneal colon has been observed to lie in a posterolateral or even a retrorenal position [5], and in these cases, there is a great risk of kidney injury with the intrarenal percutaneous approach. A retrorenal colon is more common in the area of the inferior poles of the kidneys (Figure 6.9). Retrorenal colon was found on CT scan in 1.9% of patients in the supine position, but 10% when the prone position (the more commonly adopted position for percutaneous access to the kidney) was assumed [5]. Therefore, with the patient in the prone position and before any invasive percutaneous renal procedure, retrorenal colon should be looked for, especially around the inferior poles of the kidney, using fluoroscopy [5].

## Intrarenal vessels

### Intrarenal arteries

Generally, the main renal artery divides into an anterior and a posterior branch after giving off the inferior suprarenal artery. Whereas the posterior branch (retropelvic artery) proceeds as the posterior segmental artery to

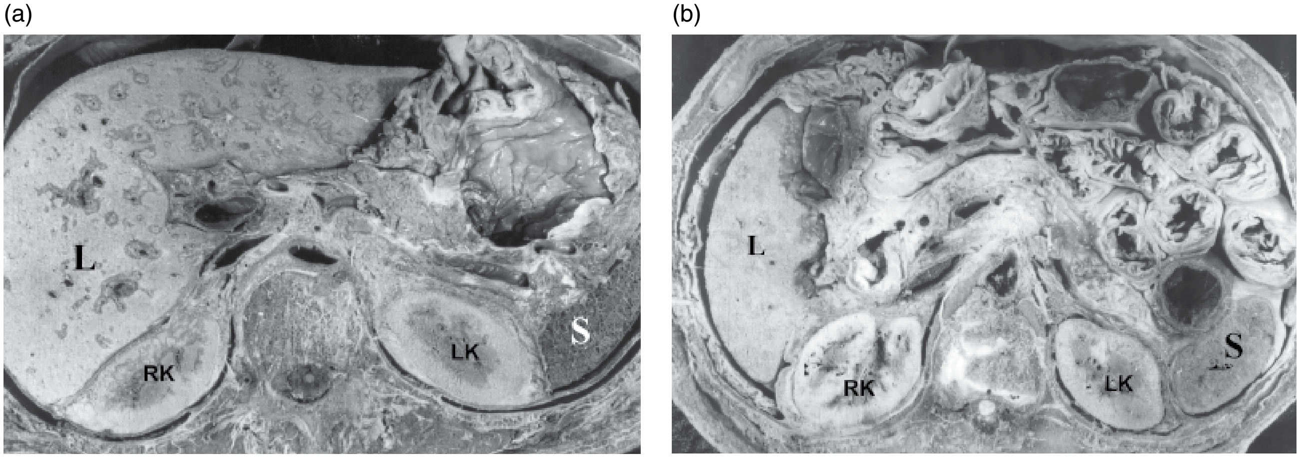

Figure 6.8 (a) Inferior view of a transverse section through a cooled cadaver at the level of the suprahilar region of the kidney. supply the homonymous segment without further significant branching, the anterior branch of the renal artery provides three or four segmental arteries. The segmental arteries divide before entering the renal parenchyma into the interlobar arteries (infundibular arteries), which progress adjacent to the calyceal infundibula and the minor calyces, entering the renal columns between the renal pyramids (Figures 6.10 and 6.11) [6]. As the interlobar arteries progress, near the base of the pyramids, they give origin (usually by dichotomous division) to the arcuate arteries (Figures 6.10 and 6.11). The arcuate arteries give off the interlobular arteries, which run to the periphery, giving off the afferent arterioles of the glomeruli (Figure 6.11) [6].

### Intrarenal veins

The intrarenal veins, unlike the arteries, do not have a segmental model. Moreover, in contrast to the arteries, there is free circulation throughout the venous system, with ample anastomoses between the veins. These anastomoses, therefore, prevent parenchymal congestion and ischemia in case of venous injury [7].

The small veins of the cortex, called stellate veins, drain into the interlobular veins that form a series of arches (Figure 6.12). Within the kidney substance, these arches are arranged in arcades, which lie mainly in the longitudinal axis. There are usually three systems of longitudinal anastomotic arcades and the anastomoses occur at different levels: between the stellate veins (more peripherally), between the arcuate veins (at the base of the pyramids), and between the interlobar (infundibular) veins (close to the renal sinus) (Figure 6.12). We have named these anastomoses as first order, second order, and third order, from periphery to center [7]. In early studies, we found three trunks (53.8%) and two trunks (28.8%) joining each other to form the main renal vein. Less frequently, we found four trunks (15.4%) and five trunks (1.9%) [7].

A detailed description of the kidney collecting system (the pelviocalyceal system), as well as the anatomic relationships between the intrarenal arteries and veins with

the kidney collecting system, which are of utmost importance for endourology, is given below.

## Pelvicocalyceal system: endourologic implications

### Anatomic classification

Recent advances in endourology have revived interest in collecting system anatomy, since a full understanding of such anatomy is necessary to perform reliable endourologic procedures as well as uroradiologic analysis [8–10]. We have proposed a pelviocalyceal classification, including all morphologic types of collecting systems, which we believe is helpful for standardizing patients and procedures [9]. This classification was derived from the analysis of 140 three-dimensional (3D) polyester resin corrosion endocasts of the pelviocalyceal system (Figure 6.13), obtained from 70 fresh cadavers according to a technique described previously [8].

#### Basic intrarenal anatomy

The renal parenchyma basically consists of two kinds of tissue, the cortical tissue and medullar tissue. On a longitudinal section (Figure 6.14), the cortex forms the external layer of renal parenchyma. The renal medulla is formed by several inverted cones, surrounded by a layer of cortical tissue on all sides (except at the apices). As in longitudinal sections, a cone assumes the shape of a pyramid (Figure 6.14) and the established term for the medullar tissue is renal pyramid; the apex of this pyramid is termed the renal papilla. The layers of cortical tissue between adjacent pyramids are termed renal columns (cortical columns of Bertin; Figure 6.14) [8, 10].

The cortical tissue is made up of the glomeruli with proximal and distal convoluted tubules. The renal pyramids are made up of loops of Henle and collecting ducts; these ducts join to form the papillary ducts (about 20), which open at the papillary surface (area cribosa; Figure 6.15) and drain urine into the collecting system (into the fornix of a minor calyx).

A minor calyx is defined as the calyx that is in immediate apposition to a papilla (Figures 6.14 and 6.15). The renal minor calyces drain the renal papillae and range in number from 5 to 14 (mean, 8); we have found 70% of kidneys to have 7–9 minor calyces [8]. A minor calyx may be single (drains one papilla) or compound (drains two or three papillae) (Figures 6.13 and 6.15). The polar calyces are often compound, markedly in the superior pole (Figure 6.13). The minor calyces may drain straight into an infundibulum or join to form major calyces, which subsequently will drain into an infundibulum (Figures 6.13 and 6.15). Finally, the infundibula, which are considered the primary divisions of the pelviocalyceal system, drain into the renal pelvis.

### Classification of the pelviocalyceal system

The analysis of 140 endocasts led us to a division into two major groups (with two intermediate varieties in each major group). This division was based on superior pole, inferior pole, and kidney midzone (hilar) calyceal drainage.

*Group A* is composed of pelviocalyceal systems that have two major calyceal groups (superior and inferior) as a primary division of the renal pelvis and a midzone calyceal drainage dependent on these two major groups (62.2%) (Figure 6.16). Group A includes two different types of pelviocalyceal system:

- Type A-I (45%): the kidney midzone is drained by minor calyces that are dependent on the superior and/or inferior calyceal groups (Figure 6.16a).
- Type A-II (17.2%): the kidney midzone is drained simultaneously by crossed calyces, one draining into the superior calyceal group and the other draining into the inferior calyceal group (Figure 6.16b). When we analyzed the endocasts with crossed calyces in the kidney midzone, we observed that the crossed calyces (laterally) and the renal pelvis (medially) bound a region (space) that we designated the "interpelviocalyceal" (IPC) region (space) (Figure 6.16b).

*Group B* is composed of pelviocalyceal systems with kidney midzone (hilar) calyceal drainage independent of both the superior and inferior calyceal groups (37.8%) (Figure 6.17). This group also includes two different types of pelviocalyceal system:

- Type B-I (21.4%): the kidney midzone is drained by a major calyceal group, independent of both the superior and the inferior groups (Figure 6.17a).
- Type B-II (16.4%): the kidney midzone is drained by minor calyces (one to four) entering directly into the renal pelvis (Figure 6.17b). Such calyces are independent of both the superior and inferior calyceal groups.

The kidney collecting system is very variable and is not symmetrical. We found pelviocalyceal systems with morphologic bilateral symmetry in the same individual in only 37.1% of the cases (26 pairs of kidneys).

Although our pelviocalyceal classification includes all morphologic types of calyces and renal pelvices, in performing endourologic procedures it is important to be aware that the collecting system anatomy is very variable. The endocast in Figure 6.18a, for example, reveals a very long and thin superior calyceal infundibulum; this anatomic formation will certainly cause difficulties in the introduction and manipulation of a nephroscope into the superior pole collecting system. The endocast in Figure 6.18b shows just the opposite aspect (both superior and inferior calyceal infundibula are short and thick); this anatomic formation will certainly make it easier to introduce and manipulate a nephroscope within the superior and inferior collecting systems.

## Comparative analysis between pyelograms and the corresponding 3D collecting system endocasts

Since standard urograms (pyelograms) show the collecting system in only one plane, it is extremely difficult for the practitioner to visualize and imagine this system in three dimensions. A full understanding of pelviocalyceal anatomy is a prerequisite for successful endourologic

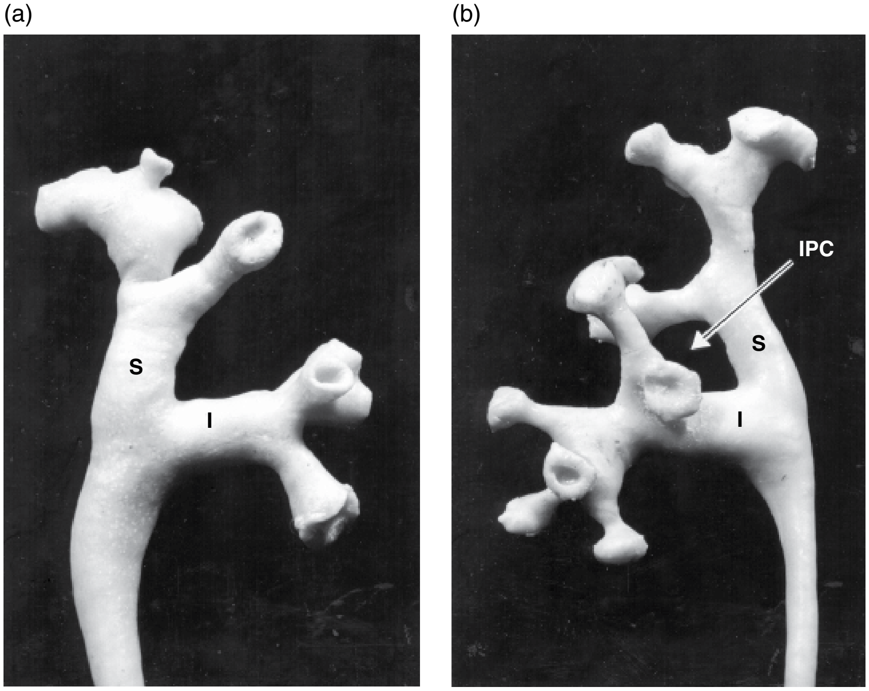

**Figure 6.16** View of the two morphologic types of pelviocalyceal systems that compose Group A. (a) Type A-I: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by calyces dependent on the superior (S) and inferior (I) calyceal groups. (b) Type A-II: anterior view of a right pelviocalyceal cast shows the kidney midzone drained by crossed calyces, dependent simultaneously on the superior (S) and inferior (I) calyceal group. This endocast shows the interpelviocalyceal (IPC) space. Reproduced with permission of Georg Theim Verlag KG.

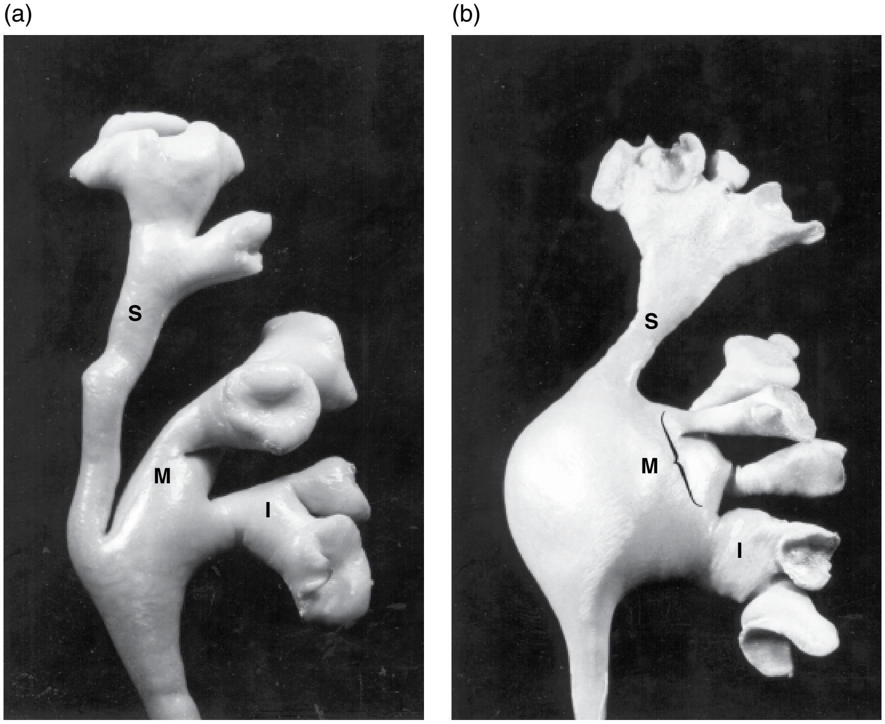

**Figure 6.17** View of the two morphologic types of pelviocalyceal systems that comprise Group B. (a) Type B-I: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by a hilar major calyx (M), independently of the superior (S) and inferior (I) major calyces. (b) Type B-II: anterior view of a left pelviocalyceal endocast shows the kidney midzone drained by minor calyces (M) entering directly into the renal pelvis, independently of both the superior (S) and inferior (I) calyceal groups. Reproduced with permission of Georg Theim Verlag KG.

interventions in the upper urinary tract, as well as for interpreting fluoroscopy pyelograms and other imaging examinations.

To assist endourologists in forming a mental image of the collecting system in three dimensions and learning the exact spatial position of the calyces, before obtaining the pelviocalyceal system endocast, iodinated contrast was injected into the ureter of 40 of our cases to opacify the collecting system to obtain a pyelogram. After radiography, the contrast was removed and the collecting system was filled with a polyester resin to obtain a 3D endocast. These 40 kidneys enabled a comparative study between the radiographic images and their corresponding 3D endocasts. This identified some remarkable anatomic aspects of the kidney collecting system that need to be considered during endourologic procedures.

### Presence of perpendicular minor calyces

In 11.4% of the endocasts (16 of 140) we found a perpendicular minor calyx draining directly into the renal pelvis or into a major calyx (Figure 6.19). The minor calyces perpendicular to the surface of the collecting system, which are seen in the endocasts, can be superimposed on other structures, which means their visualization radiographically can be difficult (Figure 6.20). Stones in such minor calyces viewed on standard anteroposterior radiographic images can appear as if they were placed in the pelvis or a major calyx. Thus, this anatomic detail must be considered in cases of stones that do not alter renal function and can appear as if they are in the renal pelvis or a major calyx. In this situation, a complementary radiologic study with lateral and oblique films must be performed to determine accurately the position and extent of the stones [11, 12].

When a stone is located in a perpendicular minor calyx (Figure 6.19), its removal presents additional difficulties for both extracorporeal shock-wave lithotripsy (ESWL) and percutaneous nephrolithotripsy (PCNL). Patients with stones in such calyces are not good candidates for ESWL because these calyces invariably present narrow infundibula (<4 mm in diameter); therefore, discharge of the disintegrated stone fragments will be difficult [13, 14]. Regarding percutaneous removal, direct access into the calyx containing the stone is easy; nevertheless, it involves a puncture without consideration of the arterial and venous anatomic relationships to the collecting system, which carries a high risk of injuring a vascular structure [12]. Therefore, in cases of stone in such calyces, safe access, techniques, and instruments should be used.

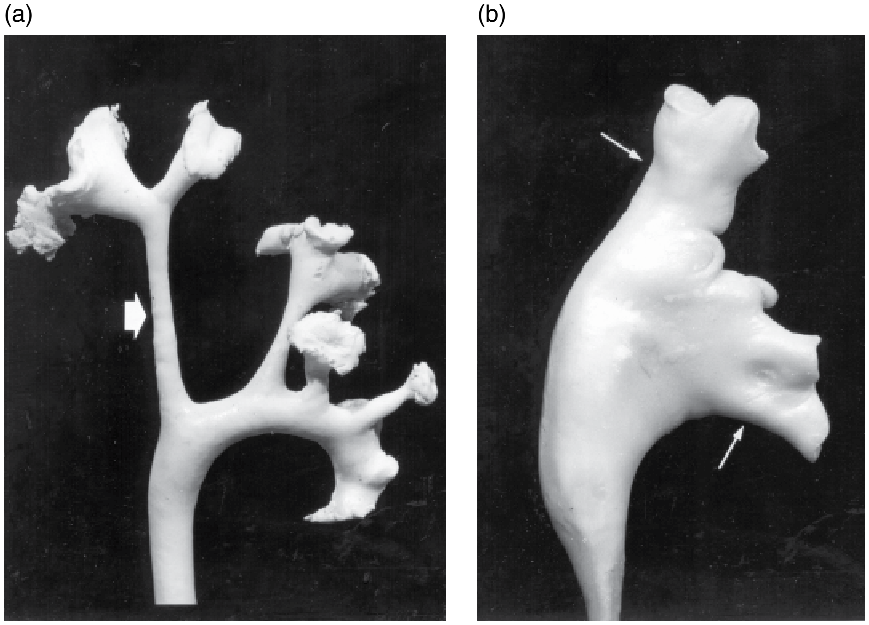

**Figure 6.18** Anterior view of two left pelviocalyceal endocasts, one showing a long and thin superior calyceal infundibulum (arrow) (a) and the other a short and thick superior and inferior calyceal infundibula (arrows) (b). Reproduced with permission of Georg Theim Verlag KG.

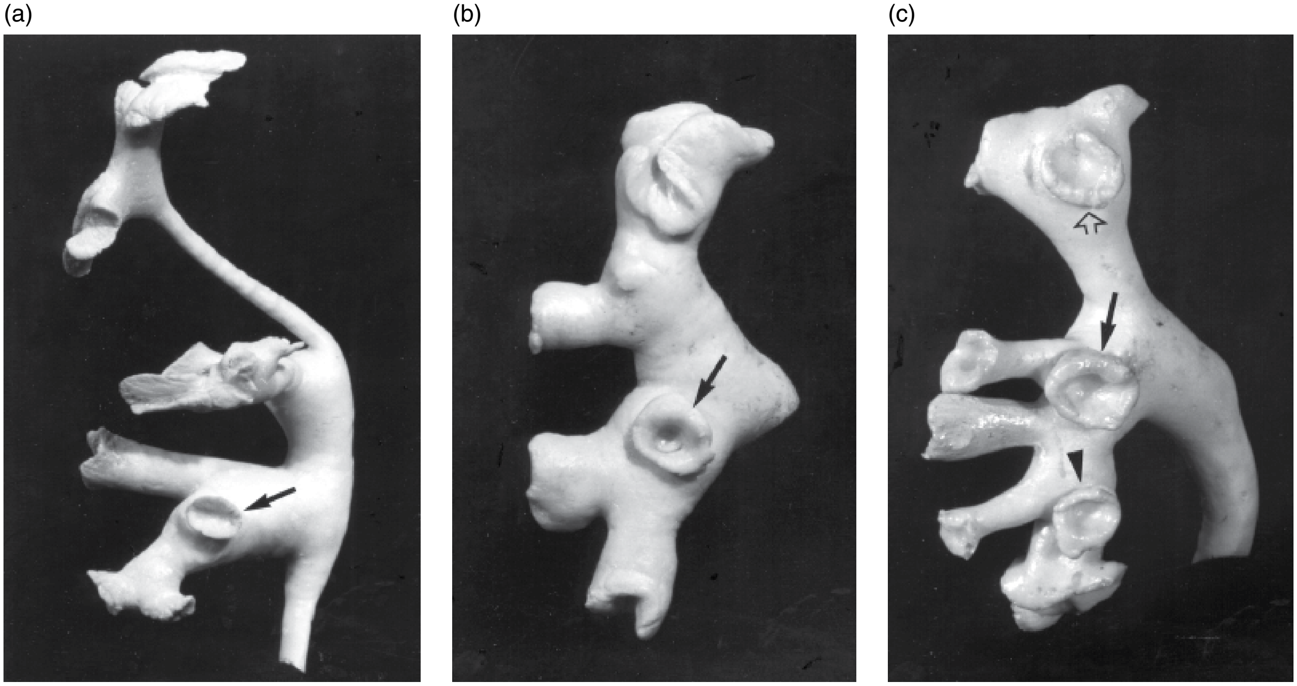

**Figure 6.19** Anterior views of a right pelviocalyceal endocast showing (a) a perpendicular minor calyx draining into the inferior calyceal group (arrow); (b) into the inferior calyceal group (arrow), very close to the renal pelvis; and (c) into the renal pelvis (arrow). This latter endocast also shows a perpendicular minor calyx draining into the superior calyceal group (open arrow) and a perpendicular minor calyx draining into the inferior calyceal group (arrowhead). Reproduced with permission of Georg Theim Verlag KG.

**Crossed calyces**

In 17.2% of the endocasts, the kidney midzone (hilar) was drained simultaneously by crossed calyces, one draining into the superior calyceal group and the other into the inferior calyceal group. On the pyelograms, the crossed calyces (laterally) and the renal pelvis (medially) outlined a radiotransparent region that we termed the interpelviocalyceal region (Figure 6.20a). In the 3D endocasts, that same region appeared as a space (Figure 6.20b) [9, 11, 12].

The interpelviocalyceal space may have different shapes: lozenge-like (the most common), long and narrow, and even small and round, depending on the shape of the

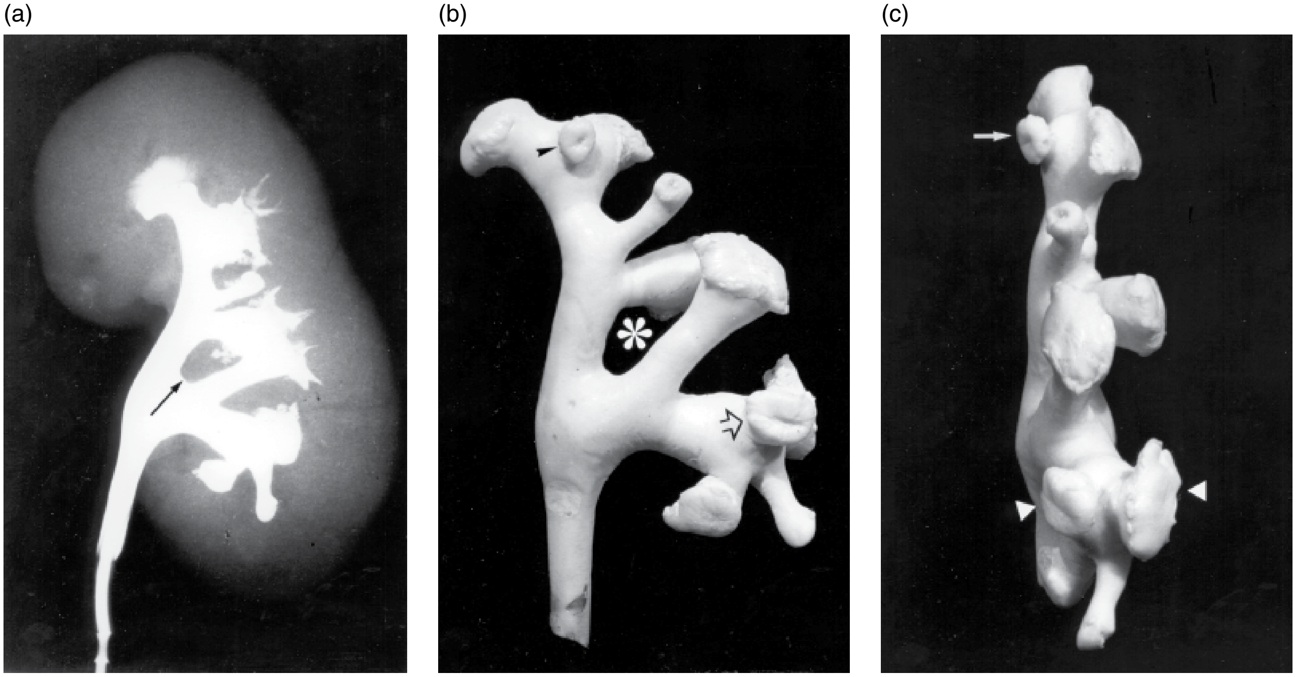

**Figure 6.20** Comparative study between radiographic view of a left kidney and its corresponding 3D endocast. (a) Anterior view of a retrograde pyelogram shows a radiographic image of the interpelviocalyceal region (arrow). (b) Anterior view of the corresponding 3D endocast. The asterisk denotes the interpelviocalyceal space; the arrowhead points to a minor calyx perpendicular to and superimposed on the surface of a superior major calyx, which cannot be seen on the pyelogram; and the open arrow points to an anterior minor calyx superimposed on the posterior minor calyx. It can be difficult to make the distinction between these features on a pyelogram. (c) Oblique view of the same endocast as in (b). The arrow points to a perpendicular minor calyx in the superior calyceal group; and arrowheads to the distinction between the anterior and posterior minor calyces, which are superimposed on the pyelogram. Reproduced with permission of Georg Theim Verlag KG.

calyces and the shape of the renal pelvis (Figure 6.21). Regardless of the form assumed by the interpelviocalyceal space, it is the result of crossed calyces in the mid kidney.

When the crossed calyces were in the mid kidney, the calyx draining into the inferior calyceal group was in the ventral position in 87.5% of the endocasts [9, 11, 12] (Figure 6.22). In some cases, even when radiographically the calyx draining into the inferior group was apparently in the dorsal position, we verified its ventral position on the endocast (Figure 6.22). This constant spatial arrangement is noteworthy for endourologic maneuvers. If the intention is to access the renal pelvis via a crossed calyx or to access a crossed calyx via the renal pelvis, it is useful to remember that the calyx draining into the inferior calyceal group is almost always in the ventral position. It is also worthy of remark that detection of an interpelviocalyceal region on the pyelograms is an indirect sign of crossed calyces in the kidney midzone.

### Position of the calyces relative to the lateral kidney margin

In 39 of the 140 endocasts (27.8%), the anterior calyces had a more lateral (peripheral) position than the posterior calyces (Figure 6.23). In 27 endocasts (19.3%), the posterior calyces were in a more lateral position than the anterior calyces (Figure 6.24). In the majority of the endocasts (74; 52.9%), the anterior and posterior calyces had varied positions: superimposed or alternately distributed (in one region the most lateral were the anterior calyces, and in another, the posterior calyces) (Figure 6.25).

Since the first choice of access to the collecting system is through a posterior calyx, much effort has been made to determine preoperatively which calyces are anterior and which posterior. Previous studies have presented contradictory results and lead to misunderstanding of this subject [15]. We have described the type of kidney collecting system found in the majority of the endocasts, in which the calyces are disposed in various positions (superimposed or alternately distributed), and can affirm that the position of the calyces cannot be defined as more lateral or more medial. Considering the large variation of position of the calyces (>50% in different positions), we believe that precise determination of calyceal position is difficult with the common radiologic methods, even using oblique and lateral views [9, 11]. To solve this problem quickly and inexpensively, during endourologic procedures, with the patient in the prone position, room air should be injected into the collecting system and this will rise to the more posterior portions of the collecting system, determining which calyces are located posteriorly (radiolucent contrast) [11, 12, 16].

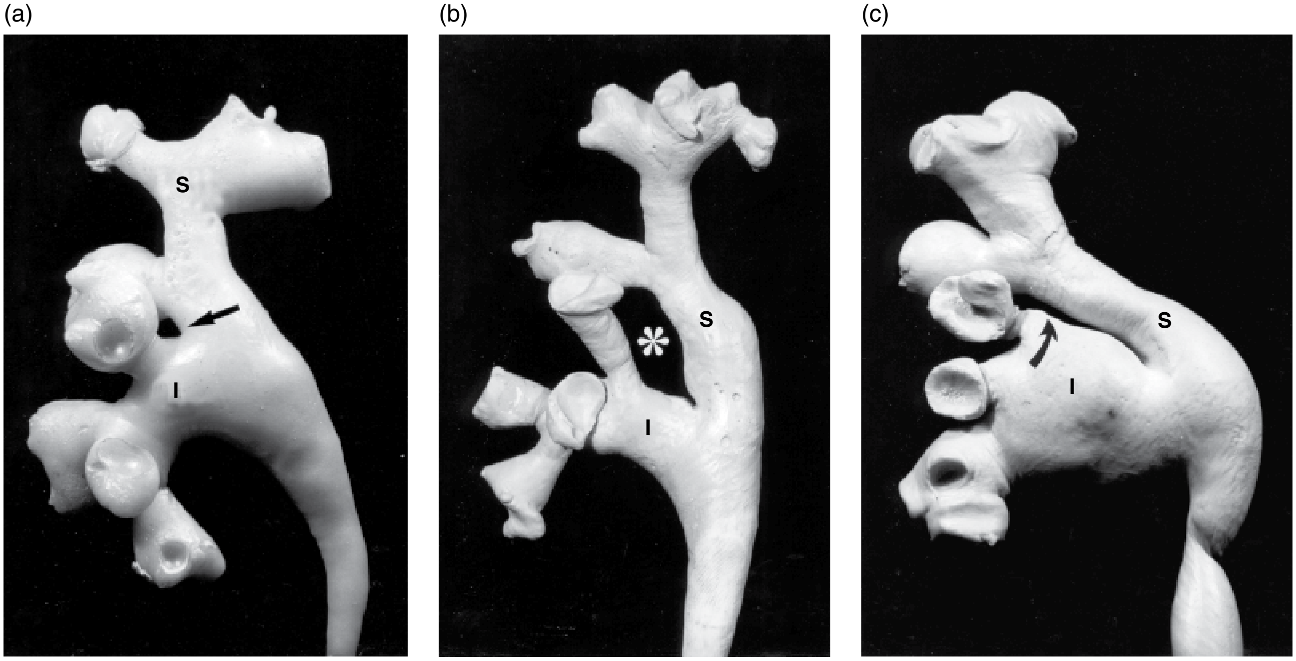

**Figure 6.21** Anterior view of right pelviocalyceal endocasts. This shows the different shapes that the interpelviocalyceal (IPC) space may assume: (a) small and round IPC space (arrow); (b) lozenge-like IPC space (most common shape) (asterisk); (c) long and narrow IPC space (curved arrow). S, superior calyceal group; I, inferior calyceal group. Reproduced with permission of Georg Theim Verlag KG.

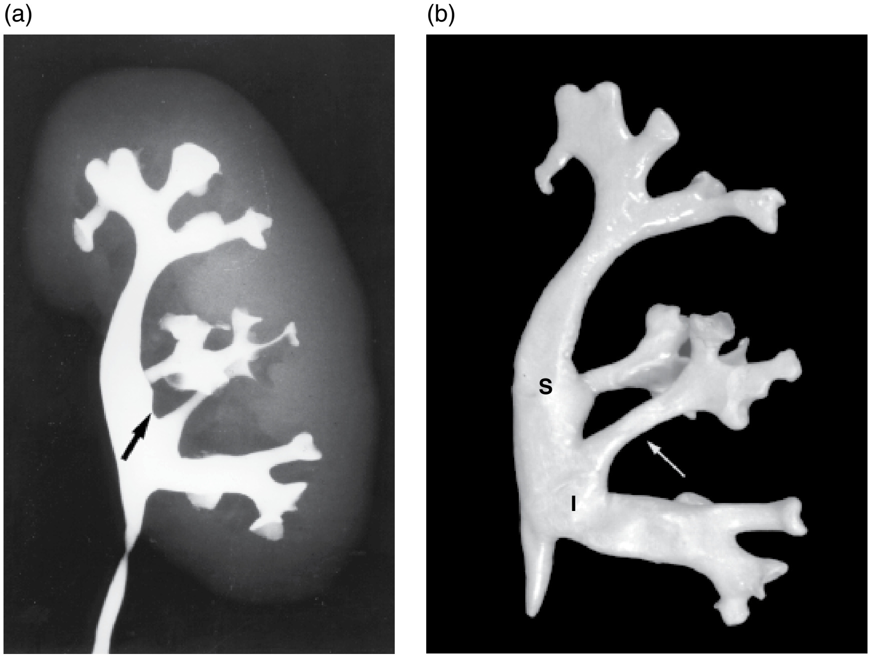

**Figure 6.22** Comparative study between a retrograde pyelogram of a left kidney and its corresponding 3D endocast of the pelviocalyceal system. (a) Anterior view of a retrograde pyelogram shows the radiographic image of the interpelviocalyceal (IPC) region (arrow). (b) Anterior view of the corresponding 3D endocast. The arrow points to the calyx which is draining into the inferior calyceal group in the ventral position (87.7% of the endocasts of the IPC space). S, superior calyceal group; I, inferior calyceal group. Reproduced with permission of Georg Theim Verlag KG.

### Position of the calyces relative to the polar regions and kidney midzone

The superior pole was drained by a midline calyceal infundibulum in 98.6% of the endocasts (Figure 6.26). The midzone (hilar) was drained by paired calyces that were arranged in two rows (anterior and posterior) in 95.7% of the endocasts (Figure 6.26). The inferior pole was drained by paired calyces arranged in two rows in 81 endocasts (57.9%) (Figure 6.26a) and by a single midline calyceal infundibulum in 59 endocasts (42.1%) (Figure 6.26b).

With regard to the calyceal drainage of the kidney polar regions, many investigators have affirmed that there usually is only one calyceal infundibulum draining

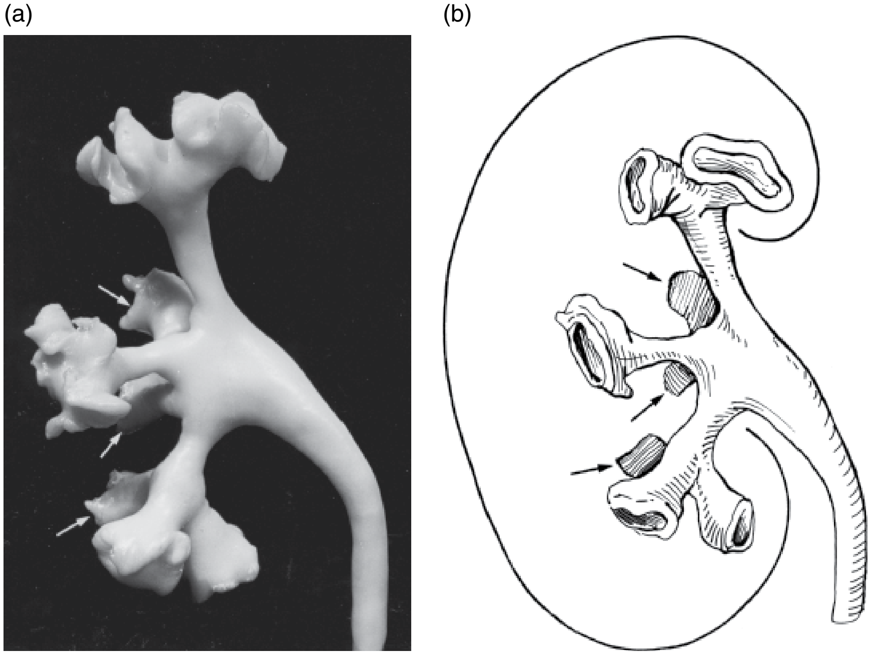

**Figure 6.23** Position of the calyces relative to the lateral margin of the kidney. (a) Anterior view of a right pelviocalyceal endocast, which shows the anterior calyces have a more lateral (peripheral) position than the posterior calyces (arrows). This means that the posterior calyces are located medially. (b) Schematic of the endocast shown in (a). This shows the peripheral calyces in the anterior plane and the medial calyces (arrows) in the posterior plane. Reproduced with permission of Georg Theim Verlag KG.

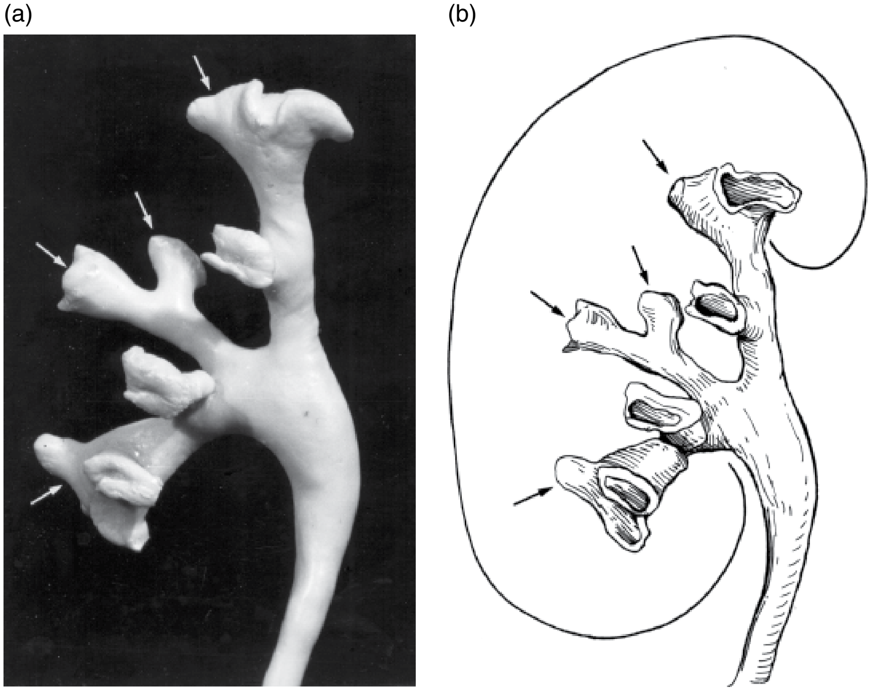

**Figure 6.24** Position of the calyces relative to the lateral margin of the kidney. (a) Anterior view of a right pelviocalyceal endocast. This shows that the posterior calyces (arrows) have a more lateral (peripheral) position than the anterior calyces. (b) Schematic of the endocast shown in (a). This shows the peripheral calyces in the posterior plane (arrows) and the medial calyces in the anterior plane. Reproduced with permission of Georg Theim Verlag KG.

each pole [3, 10, 14]. In our study, the superior pole was drained by only one midline calyceal infundibulum in 98.6% of the endocasts. However, the inferior pole was drained by paired calyces arranged in two rows in 81 of the 140 endocasts (57.9%) and by one midline calyceal infundibulum in 59 endocasts (42.1%) (Figure 6.26). These results are important in endourology; it will be easier to access endoscopically a polar region drained by a single infundibulum, which usually has a suitable diameter, rather than a polar region drained by paired calyces (Figure 6.26). Because the inferior pole is drained by paired calyces in 57.9% of the endocasts, this anatomic detail must be kept in mind, both to plan and perform the intrarenal access and endoscopic procedures in the inferior pole. The calyceal drainage of superior and inferior poles is also of utmost importance in ESWL [13, 17]. Concerning the kidney midzone (hilar) drainage, our results show that this region is drained by paired calyces

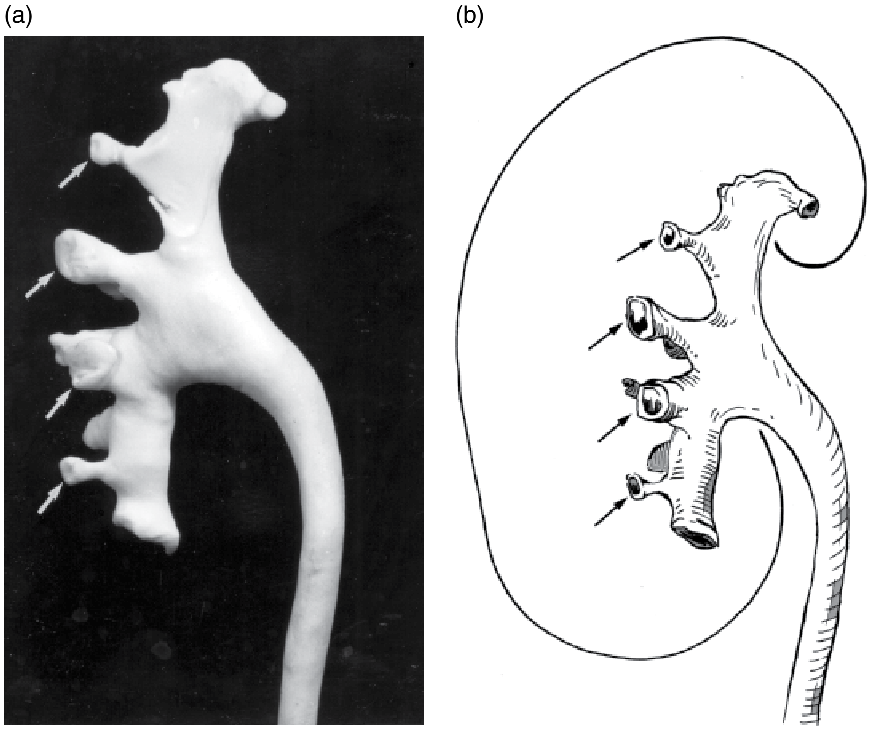

**Figure 6.25** Position of the calyces relative to the lateral margin of the kidney. (a) Anterior view of a right pelviocalyceal endocast, and (b) schematic of this endocast. The calyces in the anterior plane (arrows) are located alternately relative to the lateral margin of the kidney, i.e. in one region they are more lateral and in another they are more medial. Reproduced with permission of Georg Theim Verlag KG.

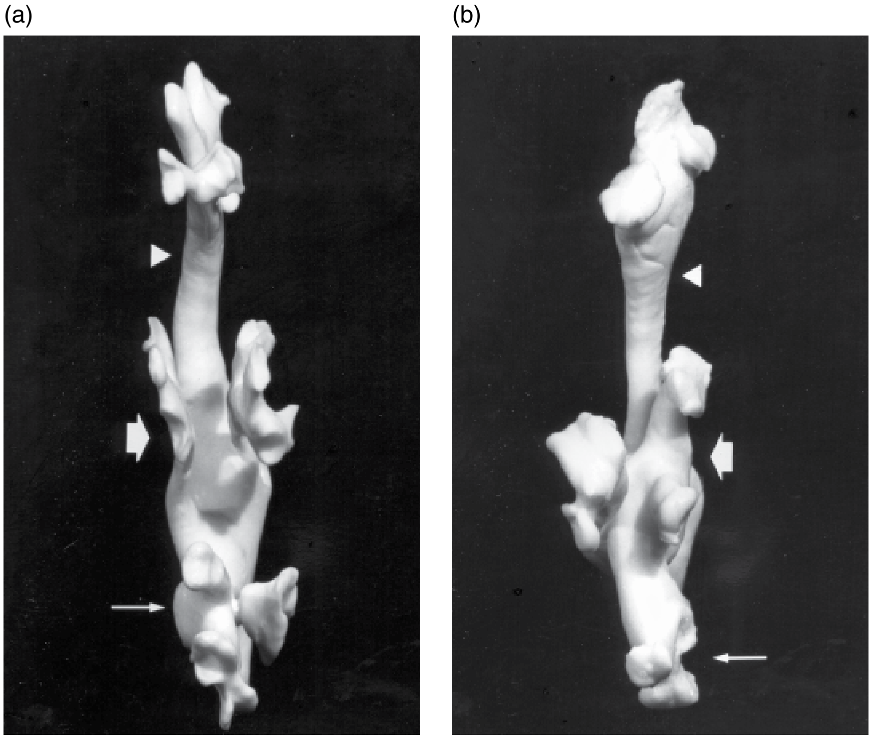

**Figure 6.26** Position of calyces relative to the polar regions and kidney midzone. (a) Lateral view of a left pelviocalyceal endocast. The superior pole is drained by a single midline calyceal infundibulum (arrowhead). The midzone (hilar) is drained by paired calyces arranged in two rows (short arrow); anterior and posterior. The inferior pole is drained by paired calyces arranged in two rows (long arrow). (b) Lateral view of a right pelviocalyceal endocast. The superior pole is drained by a single midline calyceal infundibulum (arrowhead). The midzone is drained by paired calyces arranged in two rows (short arrow); anterior and posterior. The inferior pole is drained by only one midline calyceal infundibulum (long arrow). Reproduced with permission of Georg Theim Verlag KG.

arranged in two rows (anterior and posterior) in 95.7% of the endocasts (Figure 6.26), which is of relevance to endourologists accessing and treating the mid kidney.

## Anatomic relationship of intrarenal vessels (arteries and veins) with the kidney collecting system: importance for puncture intrarenal access

Percutaneous nephrostomy is the procedure of choice for temporary drainage of urine and for gaining access to the kidney during numerous endourologic and interventional procedures. The development of new percutaneous techniques, as well as a variety of instruments, has enabled the replacement of several open surgeries by percutaneous therapy (renal abscess, calyceal diverticulum, infundibular stenosis, ureteropelvic junction obstruction, some cases of upper tract urothelial tumors, etc.) [18–20]. Percutaneous procedures are relatively invasive and complications may occur. One of the most significant complications is vascular injury that occurs when the urologist is obtaining intrarenal access. This problem may have several consequences, including intraoperative hemorrhage, hypotension, loss of functioning renal parenchyma, arteriovenous fistula, and pseudoaneurysm [21–25].

The goal of this section is to offer a detailed anatomic depiction of the intrarenal vessels and their relationships to the collecting system, and show how to perform safe percutaneous intrarenal access by keeping as many renal vessels as possible intact during puncture.

We analyzed 62 retrograde pyelograms and their corresponding 3D polyester resin corrosion endocasts of the kidney collecting system, together with the intrarenal arteries and veins, obtained from fresh cadavers.

The kidneys were punctured under fluoroscopic guidance and the endocasts obtained with needles positioned at the site of puncture (Figure 6.27). For comparative analysis, we studied kidneys that had been punctured through a calyceal infundibulum and kidneys punctured through a calyceal fornix.

### Intrarenal access through an infundibulum

Figure 6.13 shows the basic anatomy of the renal collecting system. Keeping those anatomic landmarks in mind, note that a puncture through an infundibulum (in any region of the kidney) presents clear hazards [26].

#### Superior pole

Puncture is most dangerous through the upper pole infundibulum because this region is surrounded almost completely by large vessels (Figure 6.28). Infundibular arteries and veins course parallel to the anterior and posterior aspects of the upper pole infundibulum. In our series, injury to an interlobar (infundibular) vessel was a common consequence of puncturing the upper pole infundibulum (67% of kidneys) (Figure 6.29); the injured vessel was an artery in 26% of those cases.

The most serious vascular accident in upper infundibulum puncture is lesion of the posterior segmental artery (retropelvic artery). This event may occur because this artery was crossed by and is related to the posterior surface of the upper infundibulum in 57% of the endocasts (Figure 6.30) [27]. Figure 6.31 shows an upper infundibulum puncture in which the needle tract produced complete laceration of the posterior segmental artery.

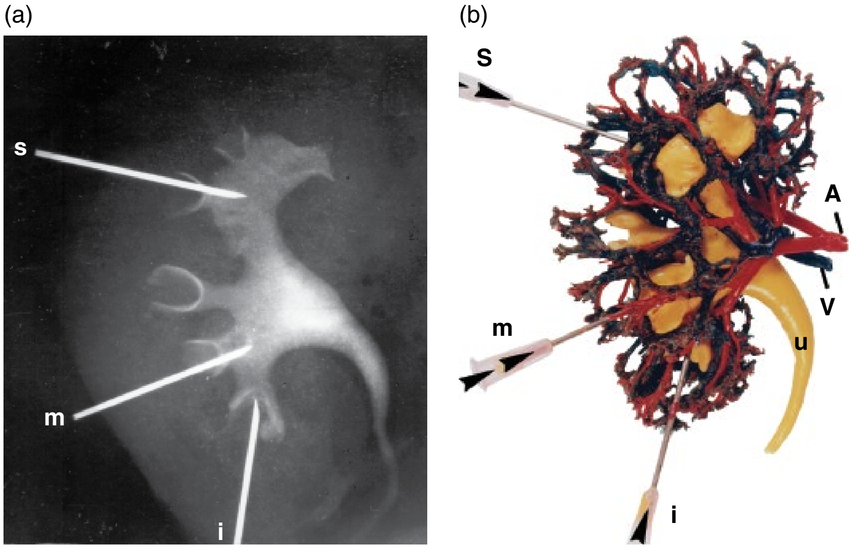

**Figure 6.27** (a) Anterior view of a retrograde pyelogram from a right kidney showing the superior pole (s), mid kidney (m), and inferior pole (i) punctures. These punctures were performed after polyester resin injections into the arterial and venous systems, while the resins were still in the gel state. Note that the injected resins are not opaque to X-rays. (b) Posterior view of the corresponding corrosion endocast obtained after contrast removal and pelviocalyceal system injection with resin. The needles are maintained in their original places. s, superior pole puncture; m, mid kidney puncture; i, inferior pole puncture. The arrowheads show the tracts of the needles. A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

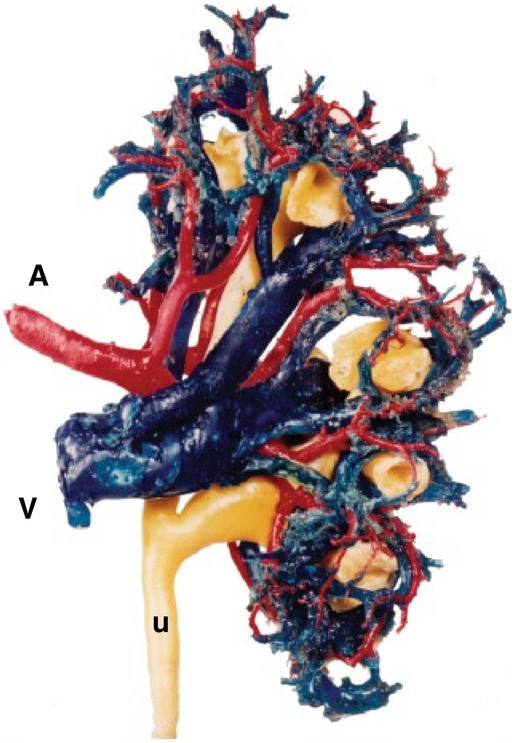

**Figure 6.28** Oblique medial view of an endocast of arterial (A), venous (V), and pelviocalyceal systems from a left kidney. This shows the upper infundibulum almost completely encircled by infundibular arteries and veins. This anatomic arrangement makes upper pole infundibular puncture especially dangerous. A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

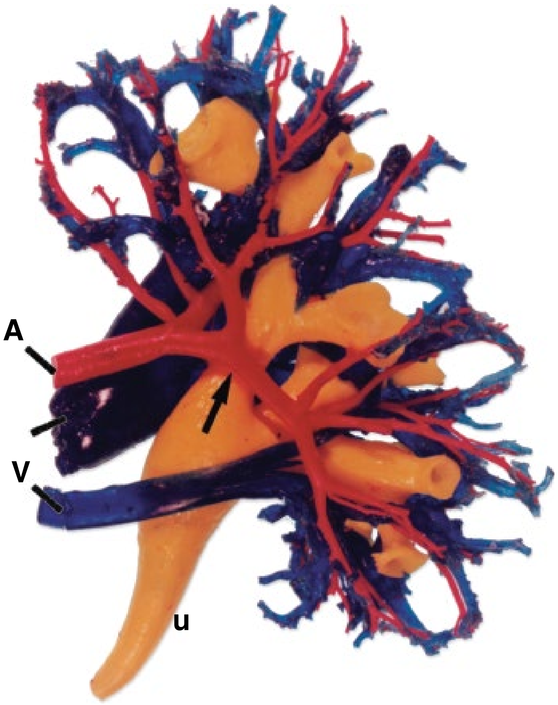

**Figure 6.30** Posterior view of an endocast from a right kidney. This shows the posterior segmental artery (retropelvic artery) crossing the posterior surface of the upper infundibulum (arrow). A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

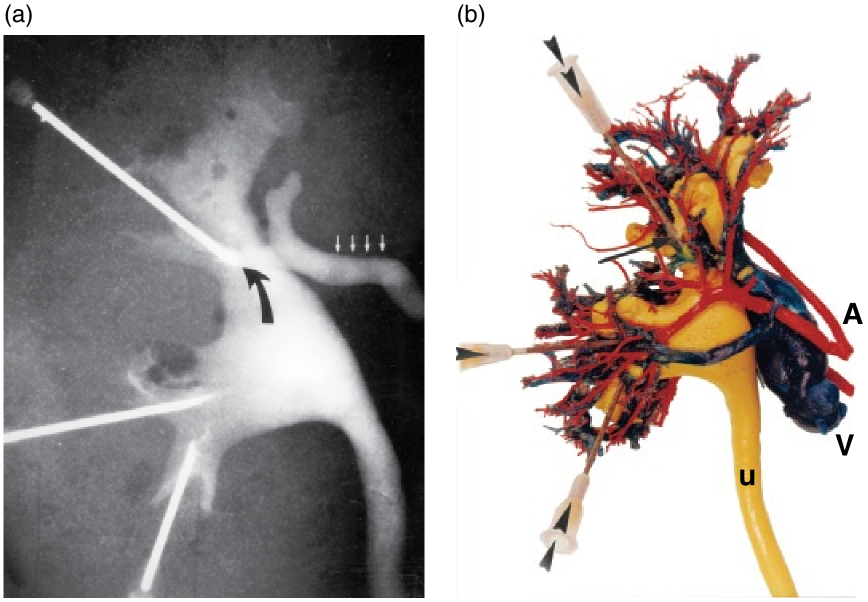

**Figure 6.29** (a) Posterior view of a retrograde pyelogram from a left kidney. Puncture performed through the upper infundibulum has injured an infundibular vein (curved arrow). Note the contrast in the retropelvic vein (short arrows).
(b) Posterior view of the corresponding endocast reveals the site of the lesion (arrow). Arrowheads show the needle tracts. A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

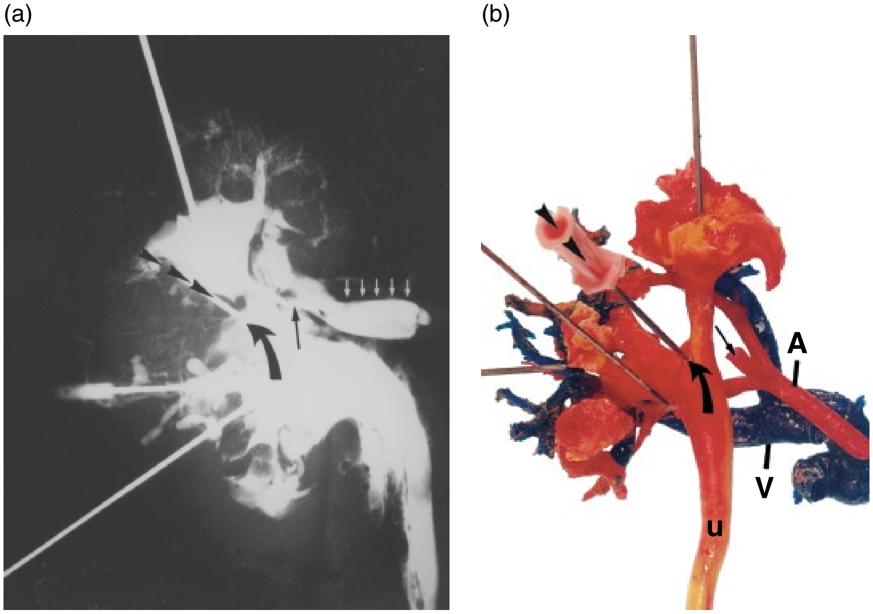

**Figure 6.31** (a) Posterior view of a retrograde pyelogram from a left kidney. This shows contrast extravasation, and contrast in the arterial system and main trunk of the renal artery (short arrows). The retropelvic artery was injured by the needle (needle tracts shown by the arrowheads). The curved arrow points to the site of the lesion; the long arrow points to the retropelvic artery filled with contrast extravasated from the collecting system. (b) Posterior view of the corresponding endocast. This shows the divided retropelvic artery (arrow) and the needle (arrowheads) responsible for the lesion (curved arrow). A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

Because the posterior segmental artery (retropelvic artery) may supply up to 50% of the renal parenchyma, injury to it may result in significant loss of functioning renal tissue, as well as causing hemorrhage [28].

### Middle kidney

Intrarenal access through the mid kidney infundibulum caused arterial lesion in 23% of the kidneys studied. The middle branch of the posterior segmental artery was injured more often than any other vessel.

### Inferior pole

The posterior aspect of the lower pole infundibulum is widely presumed by endourologists and interventional radiologists to be free of arteries. It is considered, therefore, to be a safe region through which to gain access to the collecting system and to place a nephrostomy tube. In about 38% of the kidneys examined, however, an infundibular artery was found in this region [27]. Thus, significant complications may develop as a consequence of a posterior approach through the supposedly vessel-free lower infundibulum [22, 25, 26]. We found an arterial injury in 13% of kidneys we had punctured through the lower pole infundibulum.

Concerning the veins, we found large venous anastomoses, similar to collars, around the calyceal infundibula (the so-called calyceal necks) in many of the kidneys we studied [7]. Puncture through the lower pole infundibulum therefore also risks injury to a venous arcade (Figure 6.32). A venous lesion usually heals spontaneously, but consequent hemorrhage may be problematic during the procedure.

Our findings clearly demonstrate that percutaneous nephrostomy through an infundibulum of a calyx is not a safe route, because this type of access poses an important risk of significant bleeding from interlobar (infundibular) vessels.

Infundibular puncture also creates the hazard of through-and-through (two-wall) puncture of the collecting system (Figure 6.33). Because major segmental branches of the renal artery, as well as major tributaries of the renal vein, are positioned on the anterior surface of the renal pelvis, marked hemorrhage may occur as a result of an anterior through-and-through perforation. In addition, effective tamponade of injured anterior vessels is difficult because they lie distantly in the nephrostomy tract [24, 26, 29].

Although infundibular access is feasible in some circumstances and must be considered in specific situations (e.g. some difficult anatomic cases), the surgeon must evaluate the risk of an arterial lesion, primarily in the superior pole and in the mid kidney [24].

## Intrarenal access through the renal pelvis

Direct puncture of the renal pelvis for endourologic surgery should never be performed. Besides the fact that the nephrostomy tube inserted at this site is easily dislodged and difficult to reintroduce during the operative maneuvers, renal pelvis puncture has a prohibitive and unnecessary risk of injuring a retropelvic vessel (artery and/or vein) [7, 22, 27].

## Intrarenal access through a calyceal fornix

When we made a puncture through a fornix of a calyx, venous injury occurred in fewer than 8% of the kidneys. These injuries occurred indiscriminately in the upper

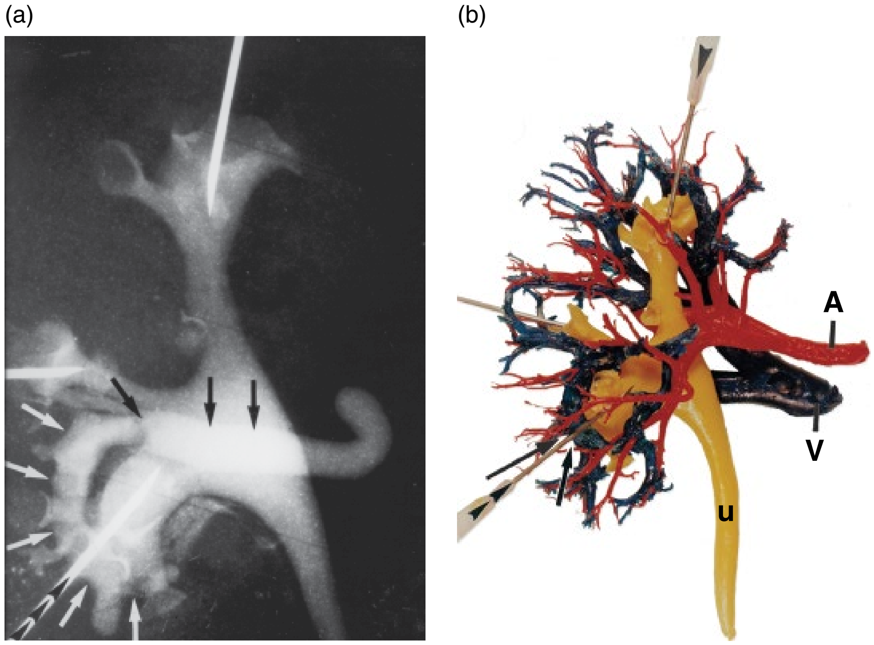

**Figure 6.32** (a) Posterior view of a retrograde pyelogram from a left kidney. This shows a puncture performed through the inferior infundibulum. A venous lesion and the contrast in a large venous arcade draining to the retropelvic vein (arrows) can be seen. The arrowheads show the tract of the needle. (b) Posterior view of the corresponding endocast reveals the site of the lesion in the venous arcade (arrows). The arrowheads show the tracts of the needles. A, renal artery; V, renal vein; u, ureter. Reproduced with permission of Elsevier.

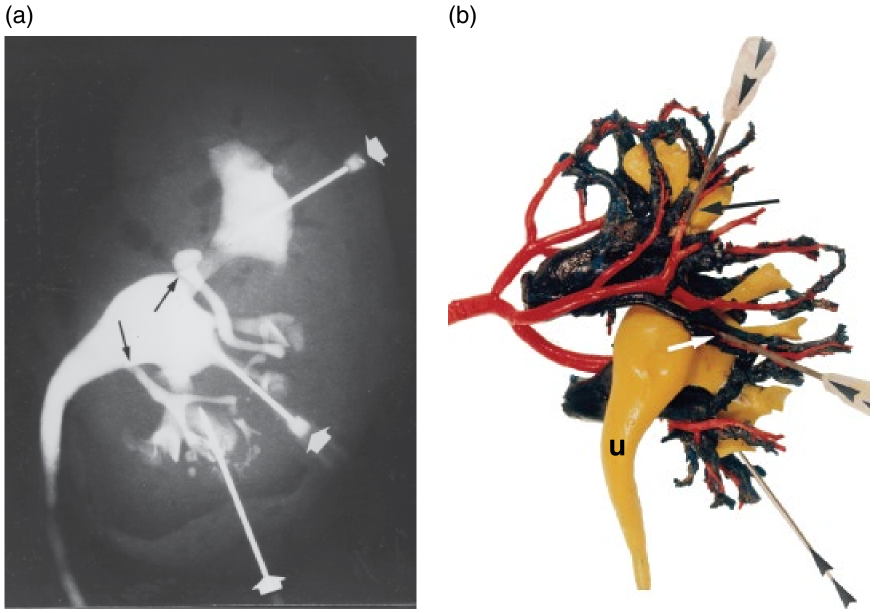

**Figure 6.33** (a) Posterior view of a retrograde pyelogram from a right kidney reveals superior, middle, and inferior punctures (short arrows) and contrast in the superior and inferior infundibular arteries (arrows). (b) Posterior view of the corresponding endocast reveals injury to an upper infundibular artery (black arrow). The mid kidney puncture (white arrow) was a through-and-through (two-wall) puncture and injured an anterior segmental artery. The injured vessel furnished the posteroinferior branch filled with contrast on the pyelogram. The arrowheads show the tracts of the needles. u, ureter. Reproduced from Sampaio et al. [24] with permission.

pole, mid pole, and lower pole calyces. We did not detect any arterial lesions as a consequence of a forniceal puncture [24].

## Where to puncture for intrarenal access

In conclusion, the high rate of vascular injury and the possibility of associated complications mean that *a nephrostomy tube should not be placed through an infundibulum of a calyx* (Figure 6.34). On the other hand, and regardless of the region of the kidney, *puncture and placement of a nephrostomy tube through a fornix of a calyx is safe* and should be the site chosen by the operator (Figure 6.35). Even in the superior pole, intrarenal puncture through a calyceal fornix is harmless (Figure 6.36). In addition, when puncturing through a fornix of a calyx, in case of lesion, injury is always to a peripheric vessel, such as a small venous arcade (Figure 6.37).

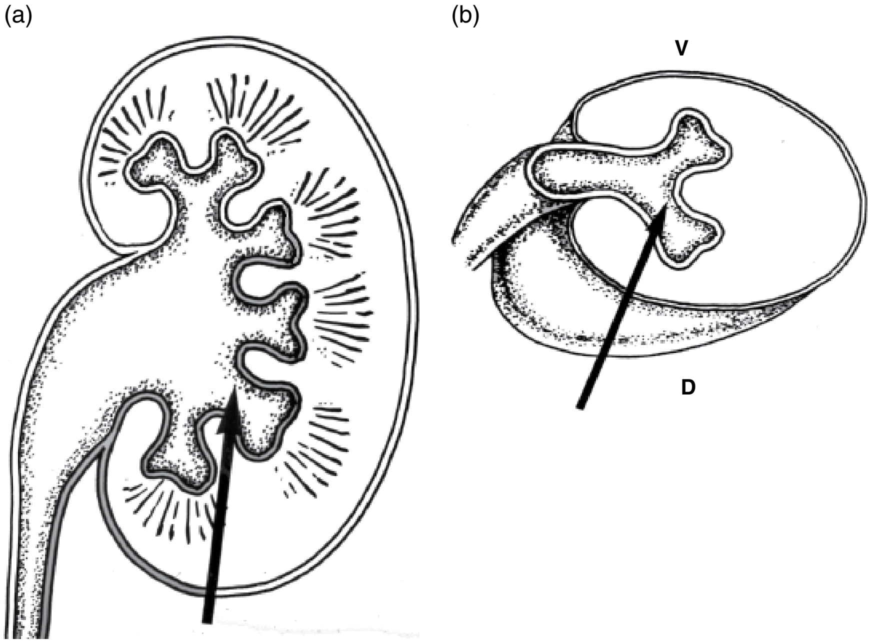

**Figure 6.34** (a) Schematic of a posterior view of a longitudinal section of a right kidney showing an intrarenal puncture performed through a calyceal infundibulum (arrow). This type of puncture should *not* be performed because it carries a high risk of vascular injury. (b) Schematic of a superior view of a transverse section of a kidney also shows an intrarenal puncture through a calyceal infundibulum (arrow); again this is *not* a recommended route. V, ventral region; D, dorsal region.

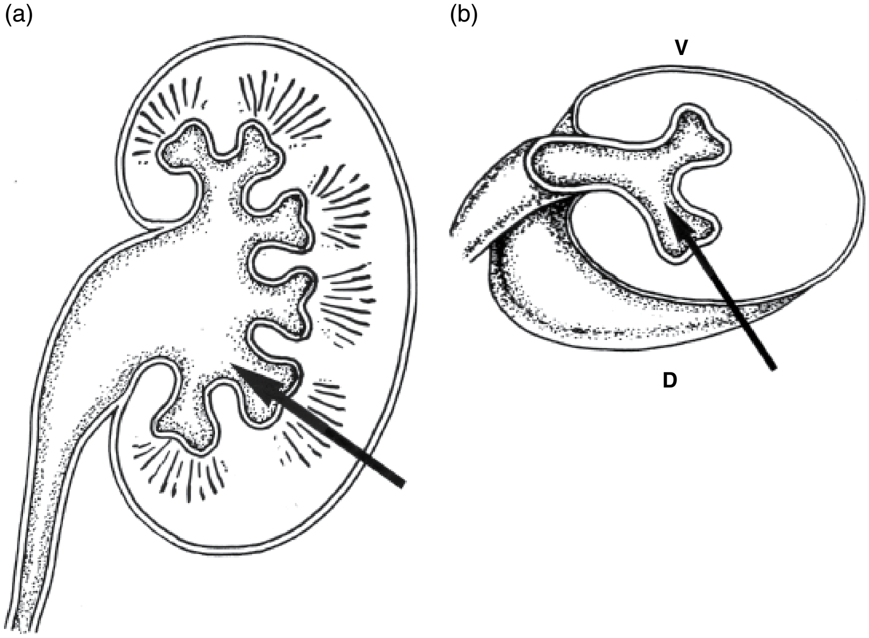

**Figure 6.35** (a) Schematic of a posterior view of a longitudinal section of a right kidney showing an intrarenal puncture performed through a calyceal fornix (arrow). This type of puncture is safe and is associated with a very low incidence of vascular injury. (b) Schematic of a superior view of a transverse section of the kidney shows an intrarenal puncture through a calyceal fornix (arrow), a route that is strongly recommended. V, ventral region; D, dorsal region.

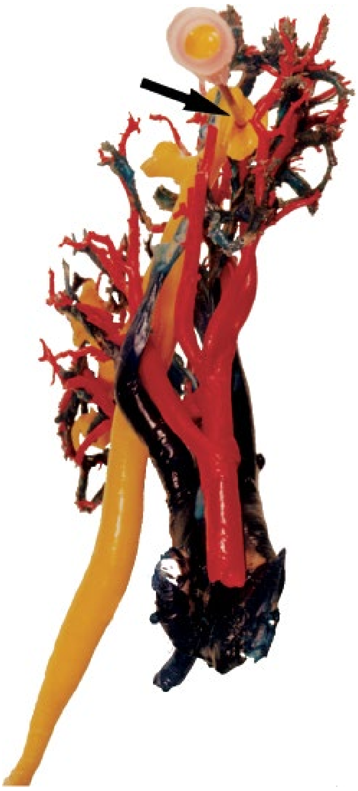

**Figure 6.36** Superior view of an endocast from a left kidney shows that, even in the superior pole, a puncture through the fornix of a calyx (arrow) is safe.

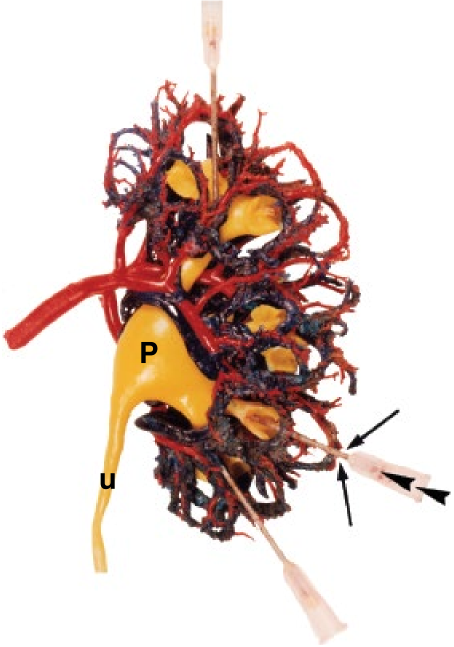

**Figure 6.37** Posterior view of an endocast from a right kidney with an inferior puncture performed through a fornix of a calyx. The arrows point to a lesion in a small peripheric venous arcade. The arrowheads show the needle tract. P, renal pelvis; u, ureter.

## Introduction

Kidney stone disease is common and affects nearly 1 in 11 individuals in the United States [1]. The majority of stones pass spontaneously; however, up to 10–20% of stones require surgical intervention. Ureteroscopy and shock-wave lithotripsy are the primary surgical methods for treating small stones while percutaneous nephrolithotomy (PCNL) is the gold standard for stones larger than 2.0 cm [2]. There are several patient- and stone-related factors that dictate the feasibility of PCNL. Stone characteristics have a significant impact on surgical outcomes and features such as size, the extent of calyceal involvement, and stone density play an important role in the decision-making process. Additional factors that should be considered are the tract length, degree of obstruction of the collecting system, pelvicalyceal anatomy, and anatomical malformations [3–7]. Efforts have been made by several groups to characterize renal stones in a standard and reproducible fashion. The importance of establishing scorings systems is twofold. First, preoperative patient counseling necessitates the development of an integrated scoring system to assess and quantify stone complexity for optimal decision-making. Second, it allows a way to account for the methodological differences among studies reporting outcomes of PCNL.

Nephrolithometry scoring systems (NLSS) aim for preoperative prediction of stone-free status (SFS) and complications through assessment of the complexity of stones before performing a PCNL. The S.T.O.N.E. nephrolithometry, the Guy's stone score (GSS), the Clinical Research Office of the Endourology Society (CROES) nomogram, and the Seoul National University Renal Stone Complexity (S-ReSC) score are the four most common NLSS used today (Table 7.1) [8–11]. These NLSS not only consider imaging criteria of stones and renal anatomy but may also use relevant patient characteristics such as body mass index (BMI), previous renal surgery, and surgeon experience.

This chapter provides a comprehensive review of NLSS used today. Their individual advantages and disadvantages will be presented along with their commonalities. Despite validation of the NLSS discussed in this chapter over 10% of members of the Endourological Society were not aware of their existence and over 85% did not use them in clinical practice [12]. An understanding of the various NLSS is critical in overcoming the methodological differences among studies that look at outcomes of PCNL and the judicious use of such systems may improve stone-free rates and reduce morbidity associated with PCNL.

## Stone scoring tools: descriptions and assessments

### S.T.O.N.E. nephrolithometry: development, reproducibility, and validation

S.T.O.N.E. nephrolithometry was developed in 2013 as a means to quantitate kidney stone complexity in a standardized and reproducible manner. The scoring system consists of the five most reproducible variables obtained from preoperative imaging. These are Stone size, Tract length, Obstruction/hydronephrosis, Number of involved calyces, and Essence of stone density measured by Hounsfield units (Table 7.2). Stone size is determined by measuring and multiplying the vertical length by the greater of the two measurements, width or length, resulting in a size in square millimeters. The tract length is defined as the distance from the center of the stone to the surface of skin measured at a 45° angle on a supine

computed tomography (CT) film. The tract length is subdivided into two scores: ≤100 mm is one point and >100 mm is two points. The obstruction component of the scoring system evaluates the degree of hydronephrosis according to the dilation of the collecting system viewed on CT imaging. Assigning a score for this variable is dependent on the user's familiarity with recognizing hydronephrosis in axial imaging. None or mild hydronephrosis is given a score of 1 while moderate to severe hydronephrosis is scored as 2. The number of

**Table 7.2** The overview of the S.T.O.N.E. nephrolithometry [9].

| | Score | | | |

| Obstruction | None | Severe | | |
| Calyces | 1–2 | 3 | Staghorn | |
| Essence | <950 HU | >950 HU | | |

calyces evaluates the extent of calyces infiltrated by the stone. This component is highly dependent on the user's understanding of renal cross-sectional anatomy [2]. If one or two calyces are involved the score of 1 is given, if three calyces are involved the score is 2, and if it is a staghorn stone the highest score of 3 is assigned. The essence component of the scoring system evaluates the stone density measured in Hounsfield units (HU) for a circular region of interest (ROI). Due to the heterogeneity of stone shape, this measurement is made by creating a circular ROI that encompasses the most stone possible while minimizing adjacent soft tissue. It is important to capture as large an area of the stone as possible in order to appreciate the average density of the stone. As most stones are lamellate in their composition, density will vary considerably from the center to the outer edges of the stone. It is important to evaluate the average density of the entire stone for the sake of reproducibility. This variable is scored based on radiodensity threshold of 950 HU. Stones greater than 950 HU are scored 2 and those less than 950 HU are scored 1.

The parameters used for the S.T.O.N.E. score are easy to calculate, do not require specialized software, and are derived from noncontrast-enhanced CT images. The methodology for choosing the associated variables were identified via a literature review of English language studies from 1976 to 2012 on MedLine to identify the most clinically relevant and reproducible variables that had been shown to impact outcomes following PCNL. The scoring system was subsequently validated in a cohort of 117 PCNL patients to evaluate the predictive value of the S.T.O.N.E. nephrolithometry. A "low" score of 4–5 demonstrated a correlation with SFS of 94–100%, a "moderate" score of 6–8 correlated with a SFS of 83–92%, and "high" scores of 9–13 correlated with SFS ranging from 27 to 64% [9]. A subsequent study demonstrated interobserver reliability, although the degree of training and levels of expertise with CT imaging clearly impacted the accuracy of grading and assessment of stone complexity. The authors found that quantifying the stone size and number of involved of calyces were least reproducible overall [13].

S.T.O.N.E. nephrolithometry has been externally validated in a number of studies. Akhavein and colleagues validated the system as a reproducible and predictive model for treatment success in 122 patients [14]. A multi-institutional study of 850 patients confirmed that the model was significantly associated with SFS, overall complications, estimated blood loss (EBL), operation time, and length of stay [15]. Studies by Labadie and Noureldin showed that the system was correlated with EBL, operative time, and length of hospital stay [16–18]. A study by Kumsar and colleagues showed that this system is effective in predicting postoperative complications [19]. This NLSS when compared to the Guy's and CROES nomogram also had more predictive ability in a retrospective review of 217 patients at a single institution [20]. S.T.O.N.E. has also been validated among a pediatric population, correlating with SFS, length of hospitalization, and complications [21].

### Strengths and weaknesses

The GSS and CROES nomograms, which are discussed later in this chapter, were initially developed using abdominal plain films, whereas S.T.O.N.E. nephrolithometry was developed on the basis of CT findings. Furthermore, because it stratifies patients into low-, moderate-, and high-risk groups, it is clinically practical for decision-making and surgical planning. Notably, S.T.O.N.E. can be calculated using only a preoperative CT, making it ideal for building a retrospective database with limited clinical information.

Additionally, the score would benefit from greater refinement of the methods used to score each of the factors to take into account their relative predictive power. It is not clear that the cutoffs used for tract length and stone density are optimal. Furthermore, the authors acknowledge the need for a standardized method to measure stone size and number of calyces involved in order to improve predictive value. A standardized definition of calyx as well as the imaging plane used to enumerate calyceal involvement would improve reproducibility. Additionally, the score assigned by degree of hydronephrosis is subjective and would benefit from stricter criteria.

## Guy's stone score: development, reproducibility, and validation

The GSS was developed to be quick, simple, and reproducible with good correlation with SFS and complication rates so that it could be used in everyday practice. An analogy might be the use of the American Society of Anesthesiologists score, which is widespread in clinical practice [22]. It was created using evidence from published data combined with knowledge and experience of senior endourologists at a single institution [11]. It consists of four grades based on stone burden and patient anatomy (Figure 7.1). The score was refined using an iterative process after evaluating 10 consecutive cases. The score was prospectively validated in 100 patients who underwent PCNL procedures in a tertiary stone center. The authors used abdominal radiography preoperatively and CT and abdominal radiography to determine SFS as defined as no stones visible or presence of clinically insignificant residual fragments <4 mm 6-weeks post-PCNL. A multivariate analysis showed that the GSS was the only predictive factor of SFS as compared to stone burden, operating surgeon, weight, age, comorbidity, and urine culture. Moreover, SFS correlated with increasing grade of GSS: grade I, 81% stone-free, II 74.2%, III 35%, and IV 29%. A higher grade correlated with the need for ancillary procedures. The authors did not find any correlation between the stone score and postoperative complications [11].

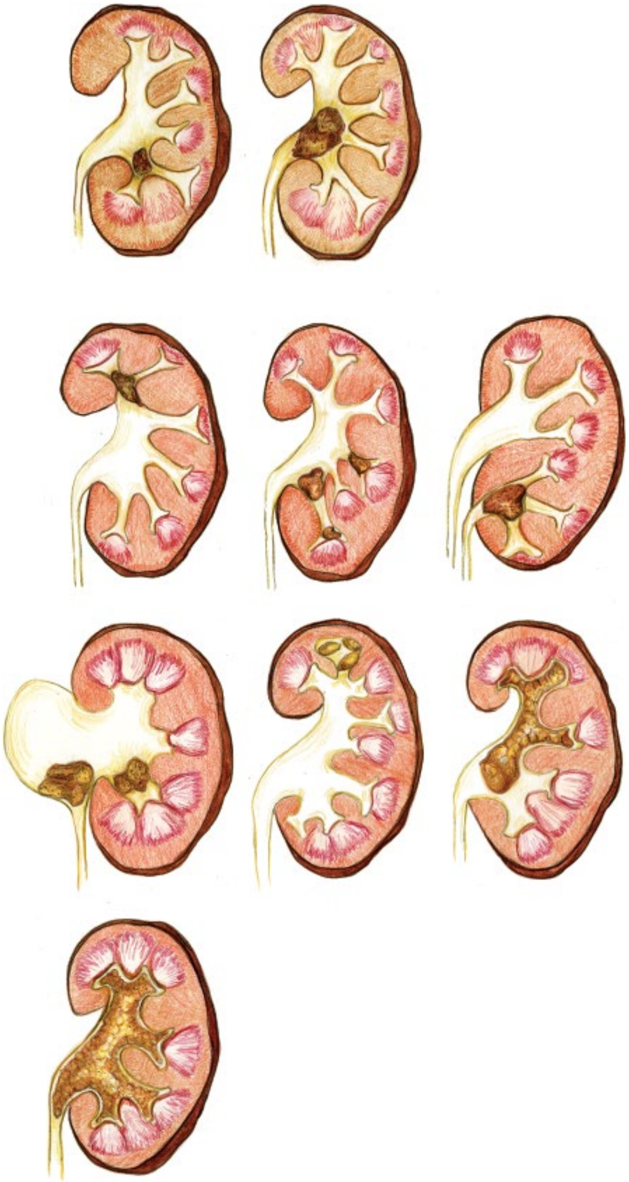

**Figure 7.1** Illustration of the Guy's stone score [11]. (Top row, left to right) Grade I: solitary stone in the mid/lower pole with simple anatomy; solitary stone in the pelvis with simple anatomy. (Second row, left to right) Grade II: solitary stone in the upper pole with simple anatomy; multiple stones in a patient with simple anatomy; any solitary stone in a patient with abnormal anatomy. (Third row, left to right) Grade III: multiple stones in a patient with abnormal anatomy; stones in a calyceal diverticulum; partial staghorn calculus. (Bottom row, left to right) Grade IV: staghorn calculus; any stone in a patient with spina bifida or spinal injury.

External validation in several series demonstrated that GSS effectively predicted SFS [15–17, 20, 23–29]. Importantly, Ingimarsson et al. and Vicentini et al. used preoperative CT to validate the GSS. Additionally, Ingimarsson et al. used a more stringent SF measurement, < 2 mm fragment, to determine SFS and confirmed a good interrater reliability [24]. Vicentini et al. also found a positive correlation between GSS and other operative outcomes such as operative time and blood transfusion rates, as well as postoperative complications [27]. A large, multicenter cohort study confirmed that the GSS score was an independent predictor of residual fragments after PCNL [15].

### Strengths and weaknesses

The GSS provides a simple, intuitive, and reproducible tool for predicting SFS following PCNL and it allows for stratifying cases between surgeons of different experience and reporting results. This NLSS has been validated in numerous studies and use of multiple imaging modalities, including abdominal radiography and CT, broadens its universal appeal and integration across varying guidelines for postoperative imaging. In addition, it takes into account patient variables, which are not included in other NLSS.

However, there are a number of key limitations to this system. First, important considerations such as stone size, calyceal involvement, density, and composition are not accounted for in this NLSS. These variables determine technical difficulty of PCNL, which have important implications for procedural success [3, 30, 31]. Second, the GSS was based on published literature and expert opinion, which are arbitrary and assume different radiological findings have the same influence on PCNL outcome. Data-driven models such as the CROES nomogram have been found to have superior predictability for SFS and also predict certain postoperative complications while the GSS does not [10]. Third, the simplicity of assigning a GSS does not account for clinical variability. For example, a patient with spina bifida and a full staghorn stone would receive the same grade IV rating even if they had just a 2 cm pelvic stone. The use of just four categories may underestimate the complexity of large kidney stones and affect the tool's ability to predict outcomes. Lastly, the overall SFS of 62% was relatively low in comparison to global overall SFS [10], raising the question of generalizability [32].

## CROES nomogram: development, reproducibility, and validation

In 2013, Smith and associates, on behalf of the Clinical and Research Office of Endourology Society (CROES) PCNL study group, proposed an alternative to the GSS. This NLSS is a statistically derived data-driven risk estimator model based on regression modeling derived from multiple institutions [10]. A total of 2806 patients from 96 centers worldwide were included in the development of the nomogram. Stone burden was the most influential patient factor that influenced stone-free rates (SFR). Additional factors that were strongly associated with SFR were case volume, prior stone treatment, staghorn stone, stone location, and stone count. Each variable is associated with the score of 0–100 and the sum of the individual scores are used to predict the SFS, defined as no visible stones or residual fragments <4 mm on abdominal X-ray 30 days following PCNL (Figure 7.2). An interpretation scale was created to associate the total score with the percentage chance of achieving SFS and bootstrapping techniques were used with 1000 cases to validate the model. Additionally, the nomogram proved clinically useful for directing treatment strategy at a threshold of 60% or more estimated SFS using a decision analysis curve [10].

The CROES nomogram was externally validated by a number of studies [15, 16, 23, 25, 28]. Specifically, Bozkurt found that the CROES nomogram correlated with SFR using CT as well as operative time, EBL, length of hospital stay, and complications [23].

### Strengths and weaknesses

The CROES nomogram is unique in that it incorporates case volume per year as a continuous variable in its calculation. This is based on outcomes of a previous study of the relationships between case volume, PCNL efficacy, and safety outcomes [33]. Moreover, the nomogram uniquely grades risk across a continuous scale rather than dividing stones of varying complexity into discrete groups.

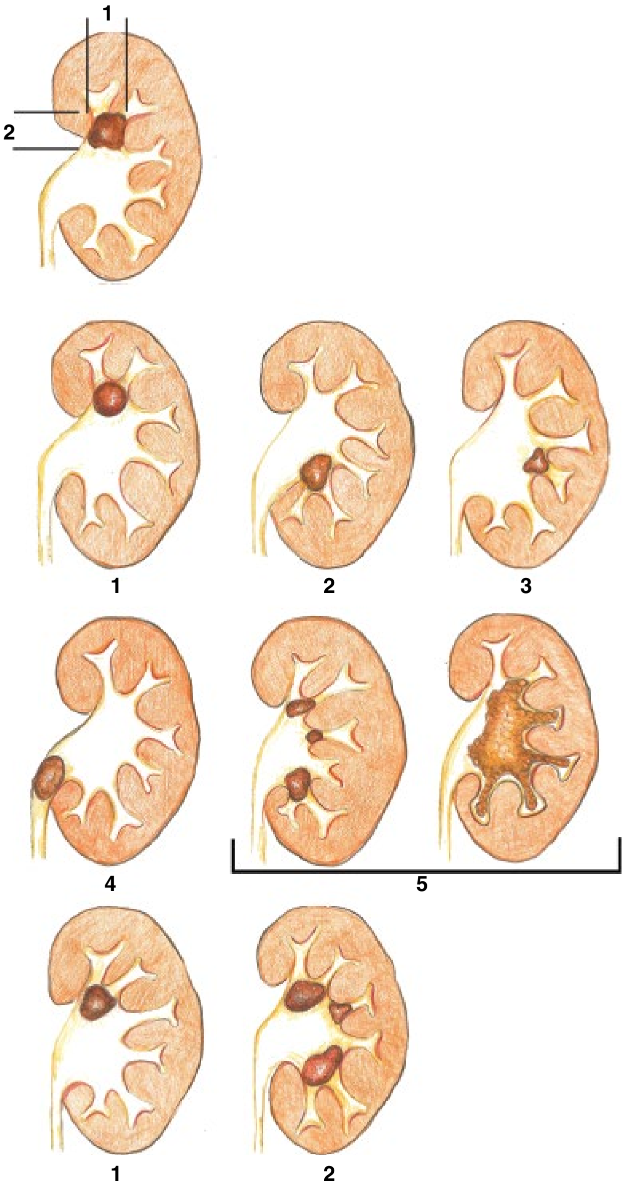

**Figure 7.2** Illustration of CROES nomogram [10]. (Top row) Stone burden. Calculate as follows: (1) measure maximum length of each stone in millimeters, (2) measure the maximum width of each stone in millimeters; (3) calculate stone burden for each stone (stone burden = 0.785 × $\text{Length}_{\max}$ × $\text{width}_{\max}$; (4) add individual stone burdens. (Second and third rows) Stone location: (1) upper calyx; (2) lower calyx; (3) middle calyx; (4) renal pelvis; (5) multiple renal locations (includes staghorn stone). (Bottom row) Stone count: (1) single; (2) multiple.

There are, however, important limitations. First, the CROES regression coefficients are derived to predict SFS and as such cannot be used to give a similar continuous predictive score for any other outcome. All that can be proved is whether scores are significantly higher or lower for outcomes other than SFS [25]. Second, the database was not created specifically for the development of a predictive model for classification of stone disease prior to PCNL and therefore lacks important variables affecting the outcomes. Third, the authors acknowledge that the study lacked radiological data on hydronephrosis and other pelvicalyceal abnormalities, each of which may influence outcomes. Fourth, the stone density and composition were not accounted for and this is known to affect the outcome of stone fragmentation and clearance [34, 35]. Lastly, the CROES design is more complicated than other available nomograms, making its everyday application challenging.

### S-ReSC score: development, reproducibility, and validation

The S-ReSC score was developed based on the assertion that the distributional complexity of stones is the most important factor that determines PCNL treatment success. A nine-point system was devised with 1 point assigned to nine specific pelvic and calyceal locations (Figure 7.3). A score of 1–2 is considered low, 3–4 is medium, and >5 is high. The score is assigned by adding the cumulative sites involved. The authors evaluated 155 consecutive cases at their center to retrospectively validate S-ReSC. The SFS for low scores was 96.0%, for medium it was 69.0%, and for high it was 28.9%. Logistic regression showed that S-ReSC significantly predicted SFS. Additionally, multiple regression analyses showed that the S-ReSC score was associated with stone number, burden, and renometry, variables that are commonly accepted as being predictive of postoperative success. It also showed that the S-ReSC score had comparatively higher predictive value than any variable alone [8].

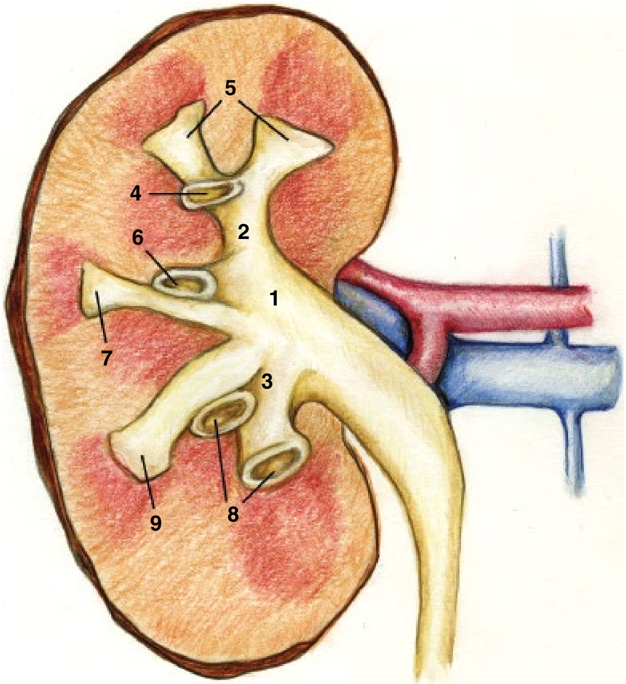

**Figure 7.3** Illustration of S-ReSC [8]. The score is calculated by counting the number of sites involved, regardless of the size and number of the stones. The sites were as follows: (1) renal pelvis; (2, 3) superior and inferior major calyceal groups (major calyx and infundibulum); and anterior and posterior minor calyceal groups of the (4, 5) superior, (6, 7) middle, and (8, 9) inferior calyx.

Studies by Choo, Park, and Jung and coworkers each externally validated the S-ReSC score. In a 327 patient cohort at two tertiary centers, Choo et al. demonstrated that it predicted SFS as defined by <4 mm [36]. Park et al. validated the S-ReSC score for retrograde intrarenal surgery (RIRS), rather than PCNL. The S-ReSC score was found to be predictive of SFS with low (1–2), intermediate (3–4), and high (5–12) scores correlated with 86.7, 70.2, and 48.6% SFS, respectively [37]. Similarly, Jung et al. validated a modified S-ReSC score for prediction of SFS after RIRS by adding additional points for hard-to-reach stones in the lower poles [38].

#### Strengths and weaknesses

The S-ReSC score is a simple, easily applicable scoring tool that predicts SFS. It is based on just a single variable, stone location, which is determined with preoperative CT and demonstrates high reproducibility as a result of this simplicity.

Importantly, the S-ReSC score relies on the hypothesis that the single variable of stone location is the ultimate predictive indicator of SFS. However, it is clear from the literature that there are many variables that have important influence on outcomes. Additionally, the score was created and validated initially with a cohort at a single center. Factors that may influence success rates in the larger Western patient population (i.e. skin-to-stone distance, a surrogate for BMI) may prove useful in broadening its application.

The four tools discussed here are summarized in Table 7.3.

## Common variables in NLSS

Stone burden and location are common variables associated with all of the scoring systems mentioned in this chapter. There are individual variables that distinguish the NLSS from one another, and this may influence surgical complexity and outcomes.

### Stone burden

It is well documented that the most important variable to predict outcomes of PCNL is stone burden [3, 16, 30, 31, 39, 40]. In the first study providing a head-to-head comparison of three nephrolithometry systems – GSS, CROES nomogram, and S.T.O.N.E. – Labadie et al. [16] found that stone burden alone had the same predictive value for SFR as did each of the scoring systems. Most urologists currently utilize stone size to estimate the complexity of the procedure and surgical outcomes;

AUC, area under the curve; IVU, intravenous urography; KUB, kidney–ureter–bladder imaging; ROC, receiver operating characteristic.

however, there is a lack of uniformity in the literature with regards to calculating stone burden [16, 41, 42]. Each of the described models uses a different algorithm for calculating the stone burden. None of these methods has been shown to be superior and so the most reproducible method that accurately reflects clinically significant stone burden should be utilized.

### Location

Stone location and distribution have a substantial impact on SFR [43]. The GSS grade is largely based on location as single stones in the lower or middle poles or renal pelvis are assigned the lowest grade while single stones in the upper pole are assigned a higher grade. The CROES nomogram goes further, assigning a different score for the renal pelvis, and lower, middle, and upper poles. S.T.O.N.E. nephrolithometry accounts for the number of calyces occupied by the stone but does not specify stone location in determining the overall score. The S-ReSC score is solely based on stone distribution as determined by the cumulative number of calyces involved but does not consider their location. The relative weight that each scoring system places on the stone location is a key determinant of how it influences the score.

### Staghorn stones

Staghorn stones are particularly challenging, requiring more complex procedures, multiple tracts and, sometimes, multistaged or multimodal treatments [41]. There is no precise definition for staghorn calculi, leading to interobserver inconsistencies [41, 42]. Mishra and colleagues created the Staghorn Morphometry, a system by which the volume and distribution of staghorn stones can be evaluated to predict the requirement for number of tracts and stages for PCNL procedures. They proposed a scoring system that classifies each stone into one of three types [44]. Mishra provides a sophisticated method to predict the number of tracts and stages required for PCNL for staghorn renal calculi; however, it only applies to one type of stone and requires complex imaging software for calculation. Whether specifying staghorn status specifically or accounting for it by proxy via stone burden is necessary for the best predictive outcome remains to be studied.

### Anatomical malformations

The influence of anatomic abnormalities on PCNL outcomes has been previously evaluated and discussed in several studies [4, 6]. However, there is no consensus on their relevance given that a number of studies have demonstrated that abnormal renal anatomy is not associated with inferior surgical outcomes [6, 45, 46]. Although anatomical variables such as duplicated collecting system, horseshoe kidneys, and calyceal diverticulum were evaluated, during the literature review in the development of S.T.O.N.E., due to the low incidence of these conditions the study was not powered sufficiently to detect a difference and therefore they were not included in the resulting scoring system. These parameters should be evaluated using a larger cohort to elucidate their impact role in the scoring system.

### Previous surgery and experience of surgeon

Only the CROES nomogram takes previous surgical intervention and caseload or experience of the surgeon into consideration, having found that both significantly impact treatment success. Previous stone treatment has a twofold informational yield. Firstly, it indicates prior therapy failure, demonstrating the complexity of the stone. Secondly, case volume and experience clearly impact surgical outcomes.

### Tract length

Skin-to-stone distance is an important parameter to predict success in PCNL. Particularly, in obese patients tract length dictates the difficulty of obtaining surgical access. Additionally, skin-to-stone distance alters the effectiveness of real-time fluoroscopy necessary for proper access. The increased skin-to-stone distance makes puncture, dilation, and securing a tract more difficult. Finally, challenges related to initial access adds difficulty to the limitations on the length of working sheaths, nephroscopes, and working instruments [47]. A longer nephrostomy tract decreases maneuverability of the nephroscope and may result in longer procedures with a lower SFR and increased complications [5, 48]. The S.T.O.N.E. nephrolithometry is the only scoring system that includes tract length. CROES included BMI, a possible correlate, in the initial analysis during the development of the system but ultimately did not find it to be predictive and therefore excluded it from the nomogram.

## Surgical complications

Risk of surgical complications is an important variable that should guide clinical decision-making. In their comparative study, Labadie et al. found that while the GSS and S.T.O.N.E. successfully predicted the length of stay and EBL, none of the three scoring systems, GSS, CROES nomogram or S.T.O.N.E., predicted surgical complications [16]. Patient factors unrelated to the stone may be more indicative of the postoperative complication risk. Borrowing from the surgical oncology literature and the concept of patient frailty, Leavitt et al. have illustrated that a patient's inability to independently perform activities of daily living is a strong predictor of complications and length of stay following PCNL [49].

## Predicting radiation time

A recent multicenter study found that patients with greater stone size, BMI, number of involved calyces, skin-to-stone distance, and S.T.O.N.E. nephrolithometry score experience increased radiation exposure during PCNL [50]. In their multivariate regression, Thomas et al. showed that patient weight, not individual GSS, was correlated with radiation time and exposure [11]. Sfoungoristos et al. found that GSS, CROES score, and S.T.O.N.E. are significantly associated with fluoroscopy time [51]. With a predictive classification system, benefits and risks of using alternative imaging modalities during evaluation of disease as well as during stone removal may be weighed against increased radiation exposure.

## Quality of life

A recent survey of the literature found health-related outcomes for stone management has revolved around the quality of life outcomes, suggesting that quality of life should play an important role in clinical decision-making. Patients with recurrent urinary tract stones report more bodily pain, depression, and lower general health scores than the general American public [52–57]. Simply measuring physiologic and biologic outcomes is not ideal. A comprehensive universal tool should not only consider procedural complexity and outcomes, but also meaningful measures for patients such as quality of life. A patient may prefer a staged ureteroscopic approach over a single-setting PCNL; these preferences should be considered.

## Applicability to multiple procedures

Finally, each system above was developed as a way of quantifying stone complexity and predicting surgical outcomes. A system which can be adapted to and therefore descriptive of multiple surgical procedures is ideal as it would allow for outcome comparisons and individualized surgical planning encompassing all available modalities. There are a number of additional systems that predict outcomes following other procedures such as RIRS and extracorporeal shock-wave lithotripsy [7, 58] but, so far, only the S.T.O.N.E. and the S-ReSC scores have been studied for its applicability to an alternate procedures [37, 59]. Understanding the relative predictive value of a universal tool for multiple treatment modalities will broaden its applicability to stone disease and allow for effective comparison between treatment options, informing clinical decision-making.

## Conclusions

Prior to surgery, patients should be provided with the most accurate information about their estimated SFS and risk of complications. Categorizing patients into low-, intermediate-, high-risk surgical groups helps surgeons to appropriately counsel patients regarding their likely postoperative clinical course and, in complex scenarios, refer patients to tertiary centers. To date, there are four NLSS that have been independently validated and each has their own strength and weaknesses. The current existing data is insufficient to state which scoring system is best.

While further research to prospectively validate these scoring systems is necessary, a NLSS should be incorporated into common practice, as this would greatly improve patient counseling, surgical planning, evaluation of outcomes, and academic reporting. It would allow reliable and accurate comparisons of treatment efficacy and quality of surgical care and facilitate the meaningful comparison of clinical studies. Furthermore, it would facilitate risk adjustment, enabling physicians to better define the nephrolithiasis disease continuum and identify patients who should be referred out to tertiary centers.

## Introduction

There are a host of diseases that can cause either unilateral or bilateral ureteral obstruction (UUO and BUO; Table 8.1). Most are well known to the urologist. In this chapter we will review patient presentation and the tools available for diagnosis. Following this, we will present data from experimental studies on both UUO and BUO.

We have been involved with research on the pathophysiology of UUO and BUO for the last 30 years. When we first began in this field the literature on the effects of UUO and BUO on the kidney focused mainly on the glomerulus and tubular function. The progression of the vasodilation and subsequent vasoconstriction of the afferent and efferent glomerular arterioles and the ultimate effect this had on renal blood flow, the glomerular filtration rate (GFR), and tubular function were initially reported. At that time, measuring effective renal blood flow (RBF) and inulin clearance, along with the usual parameters of tubular function, would be ample information to report. This progressed to reporting more information on the hormones, peptides, eicosanoids, and other vasoactive mediators that were circulating, and the effect they had on the intraglomerular vasculature and overall RBF, glomerular filtration, and tubular function.

The focus now is the interstitium, the space between the tubules. UUO is accompanied by changes in the architecture of the kidney. The most prominent interstitial change is fibrosis, and the accumulation of collagens and other extracellular matrix components. Interstitial fibrosis is characteristic of many clinical entities, including diabetes, ureteral obstruction, transplant rejection, renal ischemia, and glomerulonephritis. It has been shown in a variety of chronic renal diseases that the presence of interstitial fibrosis is a major determinant of GFR. Therefore, an understanding of the processes leading to fibrosis could eventually lead to targeted antifibrotic strategies that could allow patients to maintain, or possibly regain, renal function.

In this chapter, we will explore some of the time-tested and older information on the effects of UUO and BUO on the renal glomerulus and tubule. We will present some of the newer concepts regarding the cellular and molecular mechanisms in the development of renal fibrosis. While the information presented will expose the reader to the basics of this information, it will not be a comprehensive review of the subject (for reviews, see [1, 2]).

## Patient presentation

### Symptoms

Urinary tract obstruction can result in a wide range of symptoms, from asymptomatic (incidentally discovered) to the classic picture of renal colic. The symptom complex varies according to (i) the time interval over which the obstruction occurs (i.e. acute or chronic); (ii) whether the obstruction is unilateral or bilateral; (iii) the etiology of the obstruction (i.e. intrinsic vs. extrinsic); and (iv) whether the obstruction is complete or partial.

Acute obstruction is usually associated with flank pain that may radiate into the groin and/or ipsilateral thigh. Patients commonly experience nausea, vomiting, and chills. If the renal unit is infected, high fevers may also be present. A patient with high fever, above 38.3 °C, requires emergent urologic intervention and relief of the obstruction. It is more common to have acute UUO than BUO; however, if acute BUO occurs, the patient also may experience a sudden onset of anuria. UUO and BUO can develop over long periods of time, in which case patients are usually asymptomatic, making the diagnosis of obstruction more difficult and, in many

cases, incidental. When the obstruction is bilateral and chronic, patients may present with nonspecific complaints of an increase in abdominal girth (legwear does not fit), ankle edema, malaise, anorexia, headaches, weight gain, fatigue, and shortness of breath. They may also have symptoms reflective of uremia, such as mental status changes, tremors, and gastrointestinal bleeding. Patients with either a solitary kidney or a nonfunctioning contralateral renal unit can present with UUO and symptoms of uremia.

When the obstruction is unilateral and chronic, the patient may complain of intermittent flank pain during periods of forced diuresis, such as after the consumption of alcohol, a known diuretic. This has been referred to as a Dietls crisis, after the Polish physician, Joseph Dietl. Classically, the pain is described as a sudden excruciating pain in the kidney caused by distention of the renal pelvis, rapid ingestion of large amounts of liquid, or kinking of a ureter that produces temporary occlusion of the flow of urine from the kidney. If there is hydronephrosis associated with blunt trauma, the presenting symptom can also be gross hematuria. The extrinsic causes of obstruction usually have a more insidious and hence symptom-free presentation, whether they are unilateral or bilateral. These obstructions are usually detected incidentally during the routine clinical workup of the primary disease process. A history of the patient's voiding habits is also significant. These can vary from symptoms of a weak and intermittent urine stream, urgency, urgency incontinence, overflow incontinence, and nocturia, to barely any urination at all (i.e. complete obstruction). Finally, patients may also notice rather profound increases in their urine output, out of proportion to their fluid intake, which results from poor renal concentrating ability.

### Clinical signs and biochemical findings

The clinical signs of urinary tract obstruction are somewhat nonspecific. Obstruction is occasionally associated with an abdominal mass, usually suprapubic, but it may also be a large flank mass, palpable during physical examination, which on rare occasions can be visible. The patient may also have signs of volume overload, such as bipedal edema, pulmonary congestion, and hypertension. Laboratory data may include hematuria (microscopic and/or gross), proteinuria, crystalluria, pyuria, and urinary casts. When chronic obstruction is the predominant clinical picture, the urinary diagnostic indices are most often similar to those seen with acute tubular necrosis: an elevated urinary sodium concentration, a decreased urine osmolality, and a decreased urine-to-plasma creatinine ratio. If the obstruction is more acute and not accompanied by renal failure, the urinary indices can resemble those of prerenal azotemia: a low urinary sodium concentration and an increased urine osmolality [3]. The serum chemistry studies may demonstrate elevations of serum blood urea nitrogen (BUN) and creatinine, hyperkalemia, and acidosis.

When patients experience acute obstruction in the presence of bacterial urinary tract infection, they may present with signs and symptoms of pyelonephritis or systemic sepsis. Obstruction coexisting with infection is a true urologic emergency, and appropriate imaging studies (computed tomography [CT] scan, renal ultrasonography, or retrograde ureteropyelography) must be performed on an emergency basis. The obstruction must be relieved by either percutaneous nephrostomy or a ureteral stent.

The rationale for immediate relief of obstruction is based upon the physiology of fluid reabsorption during obstruction. After the onset of obstruction there is increased intrapelvic pressure, resulting in pyelolymphatic and pyelovenous urine back flow as well as possible forniceal rupture and extravasation [4, 5]. Accordingly, there is direct movement of urine and bacteria into the vascular tree during obstruction, resulting in a life-threatening situation. In chronic obstruction, despite a marked reduction in GFR and RBF [6], urine continues to move into the vascular system [7].

## Diagnosis

### Excretory urography

For the urologist, the intravenous urogram (IVU) has been the gold standard for the detection of ureteral obstruction in patients with normal renal function and who have no allergies to contrast material and are not pregnant. The urogram can provide both functional and anatomic details of the obstruction, as opposed to ultrasonography, which provides more anatomic detail.

Acute urinary obstruction is visualized on the IVU by (i) the obstructive nephrogram; (ii) a delay in filling of the collecting system with contrast material; (iii) dilation of the collecting system, possibly with an increase in renal size; and (iv) possible forniceal rupture with urinary extravasation [8]. Chronic cases of ureteral obstruction are usually visualized by ureteral dilation, tortuosity, and a standing column of contrast in the ureter to the point of obstruction. The kidney may demonstrate marked parenchymal thinning (either segmental or complete), calyceal crescents, and the soap bubble nephrogram [8]. *However, the IVP is rarely performed today in radiology departments.* It has essentially been replaced by the unenhanced CT scan (see below).

## Ultrasonography

The renal sonogram is a good starting point for evaluating renal units of patients who have azotemia, contrast-induced allergy, are pregnant, or are in the pediatric age group. Significant information can be obtained about both the renal parenchyma and the collecting system with no exposure to radiation, and no contrast-induced nephrotoxicity or anaphylaxis.

Hydronephrosis will appear as a dilated collecting system separating the normally echogenic renal sinus, creating an anechoic central area surrounded by parenchyma. Echoes within the collecting system may indicate an infection (pyonephrosis), hemorrhage, or a lesion of the transitional mucosa, among other diagnoses. The thickness of the renal parenchyma can be measured as an indicator of the duration of the obstruction; the degree of hydronephrosis should not be equated with the duration of the obstruction.

There are several pitfalls to the use of ultrasonography for diagnosing obstruction. Both the underdiagnosis of hydronephrosis, i.e. missing an obstruction (false negative), and overdiagnosis of obstruction due to the presence of hydronephrosis (false positive) are possible. Sonograms can be false negative as a result of an acute onset of obstruction, an intrarenal collecting system, dehydration, and the misinterpretation of caliectasis for renal cortical cysts. Sonograms can be false positive for obstruction as a result of a capacious extrarenal pelvis, parapelvic cysts, vesicoureteral reflux, and a high urine flow state [8]. Therefore, although an excellent tool for the initial evaluation of selected patients with suspected renal obstruction, the sonogram should be interpreted carefully and must be consistent with the overall clinical picture.

## Diuretic renography

The diuretic renogram is becoming more widely utilized than excretory urography for evaluation of the dilated collecting system. It provides a noninvasive measure of the relative renal function and has the ability to wash out the radiopharmaceutical agent from the dilated collecting system. There is a marked reduction in radiation dose in comparison with excretory urography, and there is no potential for contrast-induced nephrotoxicity [9].

The most widely used radiopharmaceutical agents are: (i) tubular tracers such as $^{131}$I-*ortho*-iodohippurate (OIH) and $^{99m}$Tc-mercaptoacetyltriglycine (MAG3); and (ii) glomerular tracers, namely $^{99m}$Tc-diethylene triaminepentaacetic acid (DTPA). For evaluating obstruction, the radiopharmaceutical agent of choice today is MAG3, because it is more efficiently extracted by the kidney than is DTPA, delivers a lower dose of radiation to the obstructed kidney than does OIH, and is excreted by the same portion of the tubule that responds to furosemide [9, 10]. MAG3 has been shown to provide better counting statistics and visualization of the anatomy of obstruction than do OIH and other radiopharmaceutical agents [11].

The technique of patient preparation and the timing of the administration of the diuretic, when diuretic renography is performed, are extremely important. The patients should be well hydrated before the procedure. An intravenous line may be started before the procedure [9, 12]. Patients who can void spontaneously do not require bladder catheterization. Those who cannot void spontaneously do require bladder catheterization to: (i) ensure adequate bladder drainage; (ii) reduce false-positive results; and (iii) decrease the radiation dose to the bladder and gonads. The patient's renal function is extremely important when the results from a diuretic renogram are interpreted. In the presence of a reduced creatinine clearance, it may be necessary to increase the diuretic dose to achieve an adequate flow rate and reduce the possibility of a false-negative result [13].

The timing of the administration of the diuretic after the administration of the radiopharmaceutical agent has been carefully worked out. Brown et al. determined that the urinary flow rate is 3.5 ml/minute greater at 15–18 minutes after intravenous furosemide than at 3–6 minutes after a diuretic (Figure 8.1) [14]. The traditional diuretic renogram is performed by administering the radiopharmaceutical agent and obtaining images, followed 20 minutes later by intravenous administration of the diuretic, and then measuring the half-life for the clearance of the tracer from the collecting system. O'Reilly et al. referred to this technique as the F + 20 diuretic renogram [15, 16]. Figure 8.2 depicts the various outcomes from the F + 20 diuretic renogram. Diagnostic dilemma arises with patients who show a partial

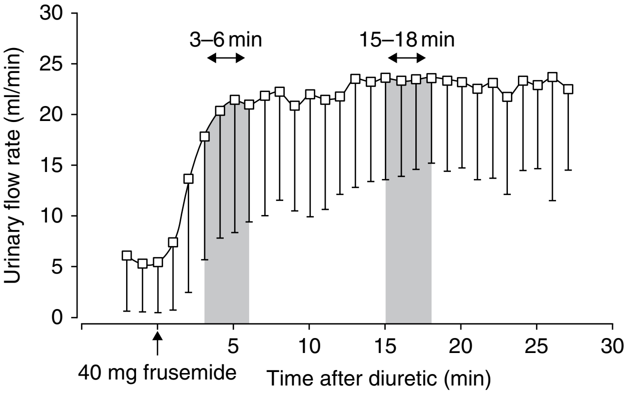

**Figure 8.1** Mean urinary flow rates following diuretic injection (error bars indicate standard deviation). Reproduced with permission of John Wiley and Sons.

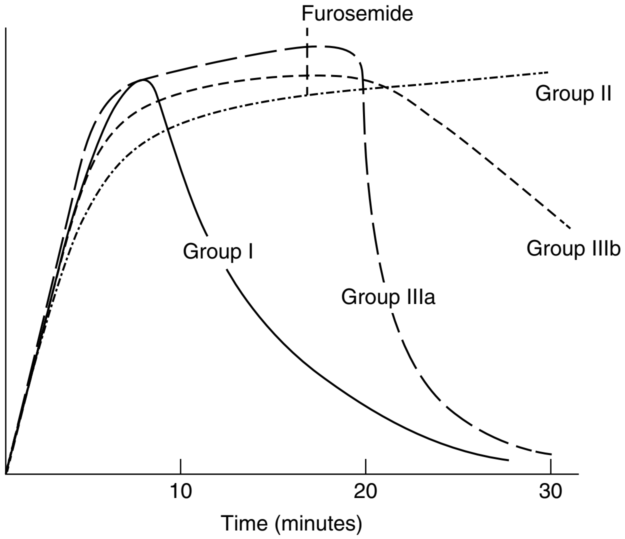

**Figure 8.2** Gamma camera renograms obtained from computer-generated regions of interest using OIH demonstrate four responses. Group I is a normal renogram. Since obstruction is sometimes unmasked by diuretic administration, O'Reilly et al. recommend a repeat renogram 15 minutes after diuretic administration. A second group I normal renogram excludes obstruction. Progressive accumulation (group II), despite administration of furosemide at about 20 minutes after tracer injection, confirms obstruction. On the other hand, rapid emptying following diuretic administration (group IIIA) despite an initial rise in the renogram curve indicates dilation without obstruction. Finally, an increasing curve with a partial excretory response may indicate either partial obstruction or renal dysfunction with an inability to respond to the diuretic (group IIIB). Reproduced with permission of Elsevier.

excretory response; this indicates either an inability to excrete the radioisotope because of poor renal function or a truly partially obstructed system (Group IIIa in Figure 8.2). Upsdell et al. were able to convert this equivocal response to the diuretic into a wash-out response by administering the diuretic 15 minutes before administering the radiopharmaceutical agent, i.e. F−15 [13]. This is the time it takes for Lasix to reach its maximal diuretic effect and thus eliminates "lag-time" as a false positive for obstruction. Some centers routinely use the F−15 technique for diuretic renography when renal obstruction is suspected. Others use the F + 20 technique for their routine diuretic renograms, reserving the F−15 technique for use when the F + 20 method demonstrates partial obstruction.

Data from the diuretic renogram can be interpreted either visually or by quantitative measurements of the half-life of the diuretic response [12]. There are many factors that influence the half-life, including: (i) renal function, which includes the level of renal maturity; (ii) compliance of the collecting system; (iii) volume of the collecting system; (iv) hydration of the patient; (v) presence or absence of a bladder catheter; (vi) radiopharmaceutical agent; and (vii) dose of the diuretic [9, 17]. It is generally accepted that a clearance of the radiopharmaceutical agent from the renal pelvis with a half-life of less than 10 minutes is normal; some experts consider a half-life of less than 15 minutes to be normal. Clearance of tracer with a half-life between 15 and 20 minutes is considered equivocal and a half-life greater than 20 minutes indicates an obstruction [9, 18].

## Whitaker test

The Whitaker test was considered the gold standard for the evaluation of upper urinary tract dilation. It provided urodynamic evidence of a mechanical obstruction of the upper urinary tract at a given flow rate. With the advent of the diuretic renogram and some of the newer radiopharmaceutical agents, the Whitaker test is not often utilized clinically. The Whitaker test is performed with the patient placed on a fluoroscopy table in the prone position. Before the patient is positioned prone, a bladder catheter is placed and connected to a pressure transducer for continuous monitoring of intravesical pressures with changes in renal pressure. A renal cannula (18G) is then inserted and connected to a pressure transducer. A combination of saline and contrast is administered via the renal cannula at a rate of 10 ml/minute. Bladder pressure is monitored throughout the procedure and its relationship to changes in renal pressure can be significant. Contrast is given along with the saline, making fluoroscopic monitoring of the anatomic site of the obstruction possible [19].

Results are separated into three categories [20]:

1) Pressure less than 15 $cmH_2O$ = nonobstructed
2) Pressures of 15–22 $cmH_2O$ = equivocal
3) Pressures greater than 22 $cmH_2O$ = obstructed.

Because the diuretic renogram is noninvasive and easily reproducible, and provides quantitative evaluation of the split and total renal function with minimal radiation exposure, it is clinically utilized more today than the Whitaker test. However, when there is extreme upper tract dilation and/or poor renal function precluding an adequate diuretic response, the pressure flow study may still have clinical utility.

## Duplex Doppler ultrasonography and renal resistive index

The use of duplex Doppler during ultrasonographic evaluation of the kidney allows the determination of the renal resistive index (RI) where [21, 22]:

$$\mathrm{RI} = ([\text{peak systolic velocity}] - [\text{lowest diastolic velocity}]) / [\text{peak systolic velocity}]$$

A value of 0.70 has been taken as the upper limit of normal [23]. RIs above 0.70 are used for the diagnosis of obstruction, although this diagnosis is not exclusive for obstruction, in as much as medical renal diseases alone can also cause the RI to exceed 0.70. An RI in the obstructed kidney that is 0.1 greater than the RI in the contralateral kidney is considered to be significant enough to indicate obstruction [24].

There is much controversy in the literature regarding the use of the RI in obstruction. Platt et al. presented data on 23 patients with acute UUO of 36 hours duration or less, measuring the RI index in the "obstructed" and the contralateral renal units [25]. The mean RI in the obstructed kidney was 0.77, as opposed to 0.60 for the normal contralateral kidney. In three obstructed kidneys with an RI of less than 0.70, two had pyelosinus extravasation and one had obstruction for less than 4–5 hours. Because the vasoconstriction of UUO occurs after 5–6 h, the RI may not rise until renal obstruction has been present for at least 5–6 hours. Platt et al. concluded that Doppler determination of renal RIs is a valuable addition for improving the accuracy of routine renal ultrasonography in the diagnosis of renal obstruction in patients presenting with acute renal colic and for whom an IVU is not desirable, e.g. pregnant patients and patients with a history of contrast-induced allergy or renal failure.

Other investigators believe there is no role for duplex Doppler sonography in the detection of acute renal obstruction [22, 26]. Tublin et al. evaluated 32 patients with acute renal colic [26]. Twelve of the obstructed kidneys had a mean RI of less than 0.70, and seven of the nonobstructed kidneys had a mean RI of greater than 0.70. Using an RI of greater than 0.70 as diagnostic of acute renal obstruction, they determined that the sensitivity and specificity of duplex Doppler sonography were 37 and 84%, respectively. When using a difference in the RI of greater than 0.10 between the ipsilateral and contralateral renal units to diagnose obstruction, they determined that the sensitivity and specificity were 37 and 100%, respectively.

The difference in clinical findings between the two studies described above may result from several factors, including: (i) the quality of the examination and the Doppler waveform analysis; (ii) the duration of obstruction; (iii) the presence of a fornix rupture and extravasation; and (iv) the degree of obstruction. Finally, Tublin et al. pointed out that the initial management of the acute renal colic with nonsteroidal anti-inflammatory drugs (NSAIDs) could alter the intrarenal vascular tone and hence affect the RI [26].

## CT and magnetic resonance imaging

Smith et al. investigated the use of noncontrast-enhanced CT in the diagnosis of acute flank pain [27]. They compared the findings in 20 patients with acute flank pain on both noncontrast-enhanced CT and IVU. CT and IVU demonstrated ureteric obstruction in 12 patients. In five of the 12, a stone was demonstrated on both studies. Six patients had a stone that was seen on noncontrast-enhanced CT and not on IVU. In one patient, a stone could not be visualized on either study, and no obstruction was demonstrated with either investigation in eight patients. Noncontrast-enhanced CT was performed at either 5 or 10 mm cuts, and all studies were completed within 5 minutes. Noncontrast-enhanced CT is more sensitive than IVU in the detection of ureteric stones in acute flank pain ($P < 0.01$). In addition, CT can provide information about extrinsic causes of ureteral obstruction, as well as nonurinary causes for the acute flank pain. CT is currently the accepted alternative to IVU especially for patients in whom the immediate use of intravenous contrast without steroid preparation is contraindicated, e.g. patients with asthma or in patients with elevations in serum BUN and/or creatinine.

Today, unenhanced helical CT is gaining widespread acceptance in many institutions over conventional CT imaging. The images are obtained faster than conventional CT scanning, often in one breath hold. The axial images can be used to create sagittal and/or coronal reformations, adding to the anatomic detail of the urinary tract and the potential for stone passage. The secondary signs of obstruction on helical CT include: (i) hydroureter; (ii) perinephric stranding; (iii) hydronephrosis; (iv) periureteral edema; and (v) renal swelling [28]. Unenhanced helical CT and conventional CT may not differentiate a uric acid from a calcium stone, necessitating a kidney–ureter–bladder (KUB) X-ray study to differentiate the stone type. However, it has been described that uric acid calculi have lower attenuation values than calcium oxalate calculi, which have very high attenuation values (1000–1570 Hounsfield units). Therefore, the differentiation of stone type is possible on the CT images [28]. It should be noted that stones formed following administration of indinavir (Crixivan) are not detectable on CT [29].

Rothpearl et al. investigated the use of magnetic resonance imaging (MRI) for the simultaneous visualization of the entire urinary tract without the use of intravenous contrast or ionizing radiation [30]. For all patients with urinary tract obstruction, a diagnosis of obstruction was made on the MR urogram. However, in eight patients in whom ureteral calculi was the source of obstruction, there was no visualization of calculi on the MR urogram. This was accomplished by comparing the urogram with a scout radiograph of the kidneys, ureter, and bladder. The point of obstruction was identified in all patients, and other etiologies for obstruction, e.g. intraluminal ureteral neoplasm and ureteral stricture disease, were well visualized. Some of the disadvantages of this technique, in addition to the inability to identify the ureteral calculus, are the image acquisition time of 34 minutes and the cost of the procedure. Additional studies comparing MRU to CT also reveal that MRU misses small calculi and mild dilatation. In addition, it is time-consuming and expensive and is limited to special situations, such as pregnant patients [31]. Again, for patients with allergies to iodinated contrast and renal failure, this technique may have its place.

## Experimental ureteral obstruction

The experimental models for ureteral obstruction include: (i) unilateral or bilateral ureteral ligation; (ii) burying the mid ureter within the psoas muscle; and (iii) placing silastic plastic tubing around the ureter to constrict the ureteral lumen.

### Unilateral ureteral obstruction

**RBF, GFR, and ureteral pressure**

The acute unilateral occlusion of a ureter will result in a characteristic triphasic relationship between RBF and ureteral pressure [32]. The first phase is characterized by a rise in both ureteral pressure and RBF lasting approximately 1–1.5 hours. This is followed in phase 2 by a decline in RBF and a continued increase in ureteral pressure lasting until the fifth hour of occlusion. The final phase ensues with a further decline in RBF accompanied by a progressive decrease in ureteral pressure (Figure 8.3). Hemodynamically, phase I is characterized by an initial afferent arteriole vasodilation [6] followed by an efferent arteriole vasoconstriction in phase II and afferent arteriole vasoconstriction in phase III [33]. The third phase of UUO, the vasoconstrictive phase, is characterized by both pre- and postglomerular vasoconstriction that reduces both RBF and ureteral pressure [32]. Yarger et al. demonstrated a marked decrease in the perfusion of the superficial cortical tissue and an increase in the perfusion of juxtamedullary glomeruli after 24 hours of UUO [34]. In addition, effective renal plasma flow (eRPF) was shown to be 55% of control values in the obstructed kidney after 24 hours of UUO [35]. Utilizing the injection of microspheres during ureteral occlusion, they also demonstrated an increase in intrarenal blood flow to the juxtamedullary nephrons, with a corresponding decrease in blood flow to the outer cortical nephrons. They believed that an increase in renin in the outer cortex relative to the inner medulla may explain the shift in intrarenal blood flow [35]. Glomerular cast studies show the poor glomerular perfusion that accompanies UUO (Figure 8.4). Arendshorst et al. confirmed with micropuncture studies that changes seen in the whole kidney by 24 hours of UUO are found at the single nephron level in association with afferent arteriolar vasoconstriction [36]. Studies using a continuous infusion of $^{51}$Cr-ethylenediamnietetra-acetic acid ($^{51}$Cr-EDTA), which allow direct measurement of GFR during obstruction, show a 75% decrease in GFR after the onset of UUO [37].

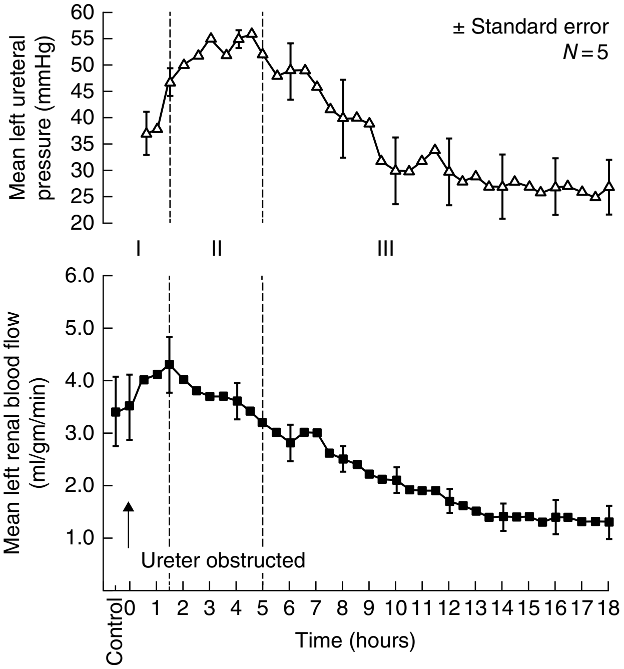

**Figure 8.3** Triphasic relationship between ipsilateral renal blood flow and left ureteral pressure during 18 hours of left occlusion. The three phases are designated by roman numerals and divided by vertical dashed lines. In phase I, RBF and ureteral pressure rise together. In phase II, the left RBF begins to decline; ureteral pressure remains elevated and, in fact, continues to rise. Phase III shows the left RBF and pressure declining together. Reproduced with permission of Elsevier.

The initial increase in RBF, which has been well characterized in the dog and rat [38], may not occur in all species. In studies in the pig, which has a multicalyceal kidney similar to humans, there is a continuing decline in RBF after onset of UUO [37]. In baboons, 12 hours of UUO was not accompanied by a significant change in RBF [39]. In the 4-week-old lamb, RBF was stable for 5 hours after onset of UUO, and declined to 71% of baseline at 5 days [40]. It is not known if the difference in the RBF response is due to the presence of a multicalyceal kidney or other factors.

Although the physiologic changes characteristic of phase I and III of UUO have been known for some time,

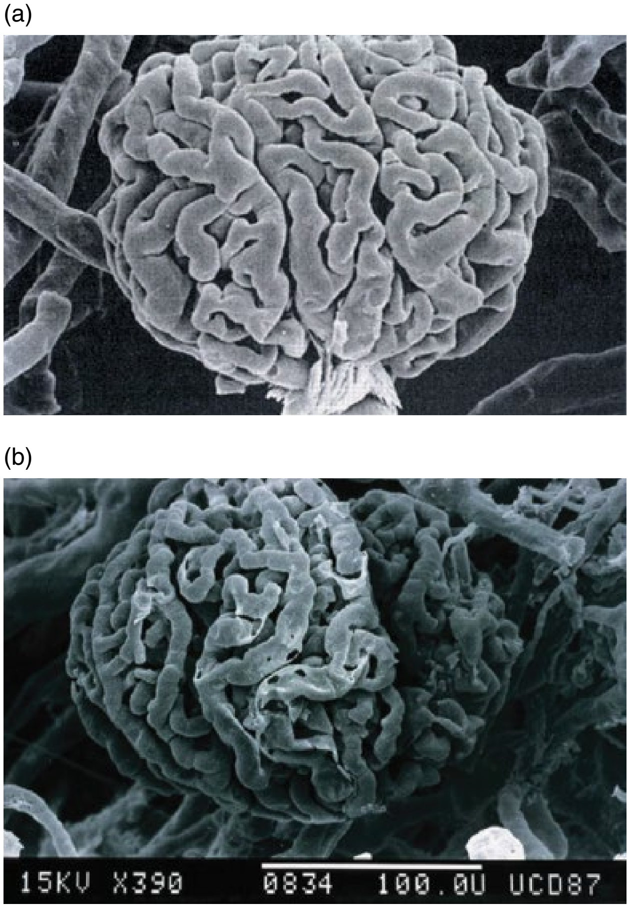

**Figure 8.4** (a) Scanning electron microscopic appearance of normal glomerular cast (magnification ×390). (b) Appearance of glomerular microvascular cast after obstruction showing capillary collapse and irregularity (magnification ×390). Reproduced with permission of Elsevier.

studies are still underway to understand the underlying cellular and molecular changes. Early studies invoked local physical interactions to explain changes in afferent and efferent arteriolar tone. Table 8.2 summarizes the effects of the various mediators on afferent and efferent glomerular arteriolar tone. However, it soon became clear that biochemical mediators were responsible for a substantial portion of these changes. Numerous studies have been carried out to determine the role of eicosanoids (prostaglandins and thromboxane), angiotensin II, nitric oxide, and endothelin in the acute and chronic changes in RBF.

## Bilateral ureteral obstruction

### RBF, GFR, and ureteral pressure

The triphasic pattern of RBF and ureteral pressure changes that characterizes UUO is not seen after BUO or unilateral obstruction of a solitary kidney. RBF increases after the first 90 minutes of BUO, as it does with UUO [41]. However, between 90 minutes and 7 hours of BUO, the RBF is significantly lower than the RBF during the same time interval of UUO (Figure 8.5a). The decrease in RBF is accompanied by an increase in renal vascular resistance during BUO to a greater level than with UUO (Figure 8.5b). However, by 24 hours of BUO, the RBF is as low and renal vascular resistance as high as with 24 hours of UUO (Figure 8.5a, b). However, ureteral pressure is higher than in UUO (Figure 8.5c). Gulmi et al. found effective RBF to be markedly decreased even at 48 hours of BUO [42]. After release of BUO, the RBF remained significantly decreased in comparison with preobstruction values for 11 hours of the study. Jaenike showed that the distribution of RBF after BUO is much different from that in the UUO model [43]. Using radioactive microspheres, he showed that 55% of RBF remains in the cortical nephrons and only 14% is shifted to the innermost renal zones. Yarger et al. used micropuncture studies to demonstrate a decrease in both whole kidney as well as single nephron clearance of *para*-aminohippurate (PAH) (17 and 55%, respectively) [44]. Solez et al., using intravenous [$^{125}$I]albumin infusion, showed a marked decrease in inner medullary plasma flow to 8% of normal by 18 hours of BUO [45].

Ureteral pressure follows a similar pattern for the first 4.5 hours of both BUO and UUO, i.e. a progressive rise in pressure (Figure 8.5c). However, after 4.5 hours of BUO,

**Table 8.2** Vasoactive mediator involvement in the hemodynamic changes of unilateral ureteral obstruction.

| | Afferent arteriole | Efferent arteriole |

| Vasodilation | Prostaglandin E2 (PGE2)<br>Prostaglandin I2 (PGI2)<br>Nitric oxide (NO)<br>Atrial natriuretic peptide (ANP) | PGI2<br>NO |
| Vasoconstriction | Angiotensin II (AII)<br>Endothelin (ET)<br>Platelet activating factor (PAF) | AII<br>ET<br>PAF<br>ANP |

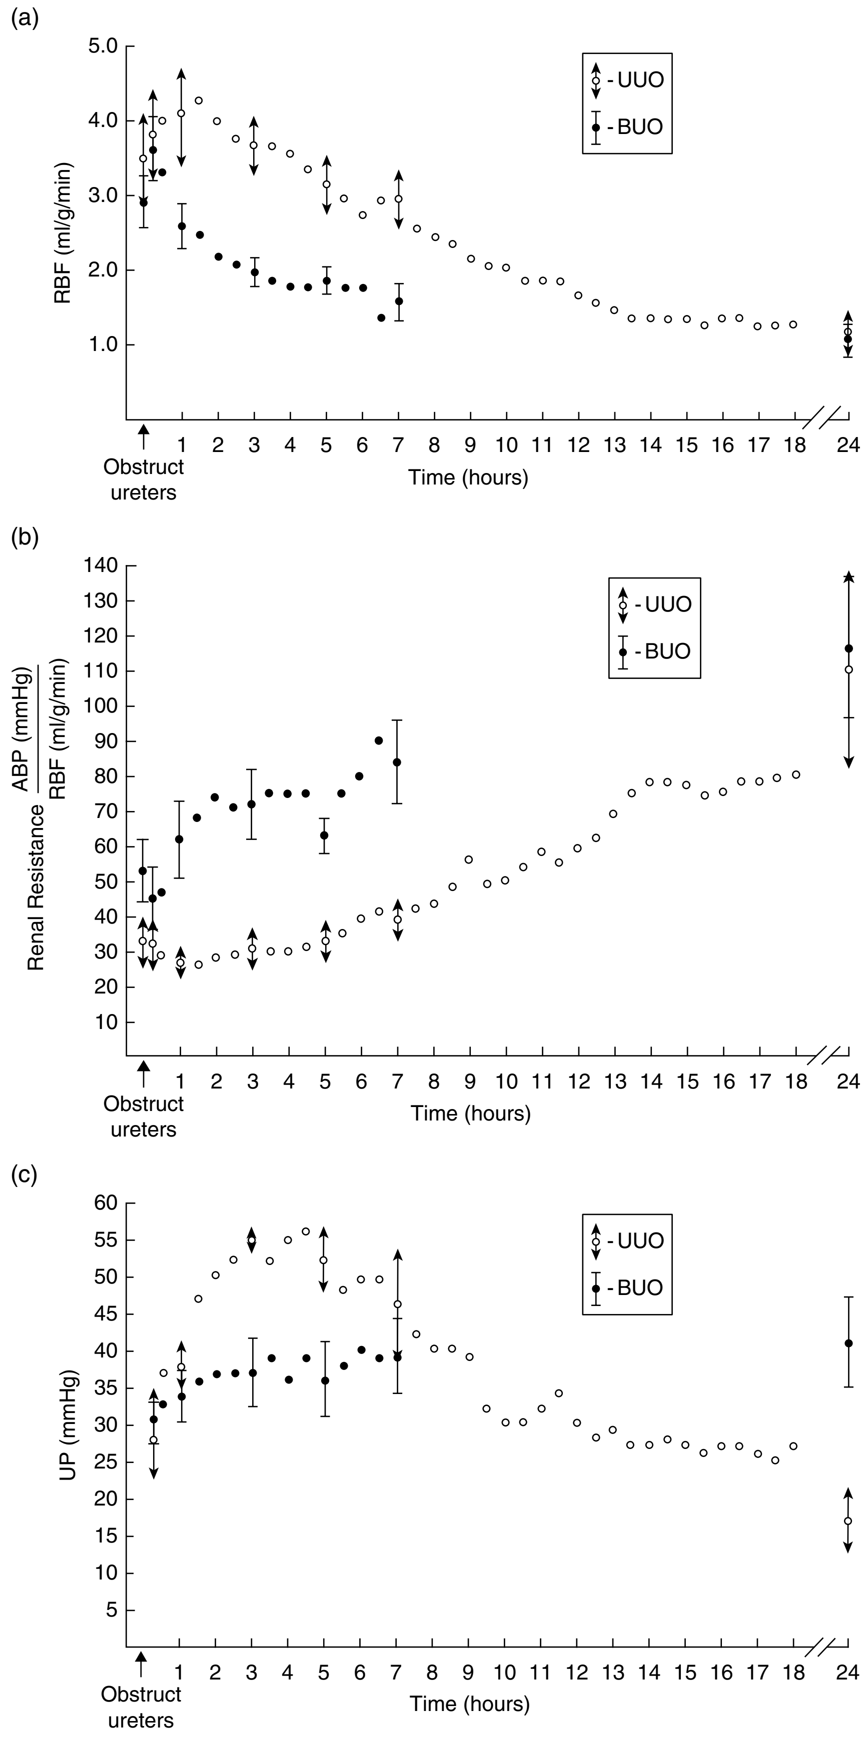

**Figure 8.5** (a) Comparison of RBF in UUO and BUO, demonstrating a similar pattern of change over the 24 hour period, although the RBF in the BUO model is below that of the UUO model from 1.5 to 7 hours postobstruction. (b) Comparison of the renal resistance (RR) in UUO and BUO demonstrating similar changes over the 24 hours period with the RR in the BUO model being higher than in the UUO model in the early hours, corresponding to the lower RBF at that time in BUO. the ureteral pressure remains elevated until 24 hours, whereas in UUO, ureteral pressure begins to progressively decline to control levels by 24 hours of ureteral occlusion (Figure 8.5c). This increase in ureteral pressure has been documented to at least 48 hours after BUO [42]. Dal Canton et al. demonstrated an increase in intratubular pressure from 14.1 to 28.9 mmHg ($P < 0.005$) with micropuncture studies in rats after 24 hours of BUO [46]. This change in intratubular pressure caused a decrease in the hydrostatic pressure gradient from 31.7 to 20.0 mmHg and a decrease in the effective filtration pressure at the afferent end of the glomerulus from 16.6 to 5.4 mmHg ($P < 0.001$). Yarger et al. also measured both proximal and distal tubular pressures during micropuncture studies of rats after 24 hours of BUO and found the pressures to be 30 and 27.7 mmHg, respectively, in comparison with 9.2 and 6.5 mmHg, respectively, in UUO rats ($P < 0.001$). The micropuncture studies of both groups have confirmed what other investigators have observed from the monitoring of ureteral pressure, a rise after 24 hours of BUO. Therein lies one of the differences between BUO and UUO. BUO passes through a phase of preglomerular vasodilation and then a postglomerular vasoconstriction and remains in this state. This explains the progressive and persistent rise in ureteral pressure despite a decrease in RBF and an increase in renal vascular resistance. In contrast, during UUO, the kidney passes through three phases: preglomerular vasodilation, postglomerular vasoconstriction and, finally, preglomerular vasoconstriction (see above).

The GFR after 48 hours of BUO is significantly decreased (22% of control values) in comparison with preobstruction GFR [42]. This decrease was also seen by Jaenike in rats after 24 hours of BUO; the GFR was reduced to 20% of the control value [43]. With micropuncture studies, Jaenike also found single nephron GFR (SNGFR) to be 34% of normal [43]. However, Yarger and Harris showed that the number of functioning nephrons, as well as the GFR of those functioning nephrons, is higher for kidneys after BUO than after UUO [47]. Harris and Yarger also demonstrated that 84% of superficial and 49% of juxtamedullary nephrons filter after 24 hours of BUO, as opposed to 40% of superficial and 12% of juxtamedullary nephrons after 24 hours of UUO [33].

Dal Canton et al. performed micropuncture studies on rats after 24 hours of BUO [46]. They observed a decrease in SNGFR after release of BUO to 40% of normal, secondary to an increase in intratubular pressure from 14 to 30 mm Hg. There was little change in glomerular capillary pressure (46 and 50 mmHg, pre- and postobstruction, respectively). With relief of obstruction, there was a 52% increase in afferent arteriole resistance, resulting in a low SNGFR in the postrelief period. Therefore, in both BUO and UUO, there is a decline in SNGFR after 24 hours of ureteral occlusion. In UUO this is secondary to an increase in afferent arteriolar resistance, whereas in BUO it is secondary to a rise in intratubular pressure with little change in afferent arteriolar resistance (Table 8.3).

**Table 8.3** Comparison of the effects of UUO and BUO in glomerular hemodynamics. Reproduced with permission of Elsevier.

| | $P_T$ | $P_G$ | AAPF | $R_a$ | SNGFR |
|---|---|---|---|---|---|
| 24 hours UUO | = = = | ↓ | ↓↓ | ↑↑ | ↓↓ |
| 24 hours BUO | ↑↑ | = = = | = = = | = = = | ↓↓ |

AAPF, afferent arteriole plasma flow; $P_T$, intratubular pressure; $P_G$, hydrostatic pressure across glomerular capillaries; $R_a$, resistance of single afferent arteriole; SNGFR, single nephron GFR.

### Involvement of atrial natriuretic peptide

Several investigators have postulated the accumulation of a "substance" during BUO that would affect the glomerular hemodynamics in such a way that there would be preglomerular vasodilation and postglomerular vasoconstriction, as seen with late-phase BUO. This substance would not accumulate during UUO, because it could be excreted by the contralateral kidney. Wilson and Honrath demonstrated such a substance with cross-circulation studies in rats [48]. When the cross-circulation was between a donor rat with 24 hours of BUO and a normal recipient rat, there was an immediate increase in both sodium and water excretion. This did not occur when the donor rat was subjected to 24 hours of UUO.

Harris and Yarger also postulated the existence of a circulating diuretic factor that accumulated only during BUO [49]. They observed an increase in urine flow and sodium excretion after relief of BUO, UUO with contralateral nephrectomy, or UUO with the continuous intravenous reinfusion of urine from the contralateral kidney. In contrast, the UUO-alone animals did not have postobstructive diuresis and natriuresis.

The discovery of atrial natriuretic peptide (ANP) paved the way for studies on the role of ANP in BUO. ANP has several physiologic effects, including vascular smooth muscle relaxation, i.e. vasodilation, natriuresis, and diuresis. The natriuretic and diuretic actions of ANP have been shown to be caused by: (i) an increase in GFR through afferent arteriole vasodilation and efferent arteriole vasoconstriction; (ii) an increase in glomerular capillary ultrafiltration coefficient (Kf); and (iii) inhibition of the glomerular–tubular feedback mechanism [50]. These glomerular hemodynamic effects point to ANP as the circulating diuretic and natriuretic substance postulated by previous investigators to explain the observed changes in RBF, ureteral pressure, and glomerular filtration during BUO.

**Table 8.4** Differences in tubular function after release of unilateral and bilateral ureteral obstruction (24 h).

| | Control | Unilateral | Bilateral |
|---|---|---|---|
| Postobstructive diuresis | | Absent | Present |
| Percent of filtration excreted (V/GFR) | 1% | Decreased to 0.5% | Increased to 18% |
| $Na^+$ excretion fraction filtered | | | |
| Proximal tubular reabsorption | | Decreased | Decreased |

Fried et al. demonstrated an elevated level of plasma ANP in rats after 24 hours of BUO, but not after 24 hours of UUO (393 vs. 261 pg/ml;, $P < 0.01$) [51]. Purkerson et al. have shown plasma ANP levels of 400 pg/ml in rats with 24 hours of BUO, in comparison with 71 pg/ml in rats with UUO ($P < 0.01$) and 81 pg/ml in controls ($P < 0.01$) [52]. Elevated ANP has also been demonstrated in patients with either BUO or UUO of a solitary kidney, or in volume-replete dogs after 48 hours of BUO [42, 53].

With the demonstration of elevated levels of ANP in BUO, it became clear that ANP was likely the factor previously postulated by Wilson and Honrath [48] and Harris and Yarger [49]. The stimulus for the elevated plasma ANP seems to be an increase in intravascular volume, as determined by an elevation in pulmonary capillary wedge pressure and body weight in volume-replete dogs with BUO [42]. In support, clinical studies in patients on chronic hemodialysis show that intravascular volume, and not the degree of renal failure, is the stimulus for an elevation in their plasma ANP levels.

### Other mediators

Reyes et al. have examined the role of NO in BUO [54]. When N-NAME, an L-arginine antagonist, was infused, there was a further decrease in GFR and eRPF compared to controls, suggesting that NO was maintaining GFR and eRPF during BUO. This was confirmed by showing that there was an improvement in GFR and eRPF, as well as a decrease in renal vascular resistance with the infusion of L-arginine into rats with unilateral release of 24 hours of BUO. Other factors may also be involved in BUO. Reyes and Klahr demonstrated that antibodies to either platelet activating factor, endothelin, or vasopressin can ameliorate changes in GFR and eRPF either during or after release of BUO [55–57].

### Tubular changes in BUO

There are differences between tubular function after release of BUO and UUO (Table 8.4). Several investigators have described marked diuresis and natriuresis after the relief of either BUO or UUO of a solitary kidney in humans [53, 58–61]. Maher et al. described a significant increase in urine volume and sodium excretion after relief of obstructive uropathy [57]. The urinary flow more closely followed the osmolar excretion than the sodium excretion in this patient study. The predominant urine solute during this osmotic diuresis was urea, accounting for 37–68% of the total urine osmolality. When serum urea returned to normal, the diuresis ceased. Maher et al. therefore postulated that the physiologic diuresis was caused by a high serum urea concentration, which ceased when the BUN returned to normal.

Muldowney et al. measured total exchangeable sodium to determine whether the postrelease natriuresis of BUO is pathologic or merely a physiologic elimination of excess body sodium [62]. They found that patients with chronic obstructive uropathy had an increase in total exchangeable body sodium before release of obstruction. After relief of the obstructive uropathy, total exchangeable body sodium levels returned to normal within 2–3 weeks. The loss of sodium in the urine did not result in clinical sodium depletion in any of the patients. Muldowney et al. concluded that the increased loss of sodium in the urine upon release of chronic obstructive uropathy is a physiologic reduction of excess body sodium to normal levels.

Gulmi et al. described nine patients with obstructive uropathy and postobstructive diuresis and natriuresis [53]. Patients with obstruction had a significantly elevated plasma ANP, in comparison with the control group of patients (Figure 8.6). There was an increase in both absolute and fractional excretion of sodium that subsided with improvement in renal function.

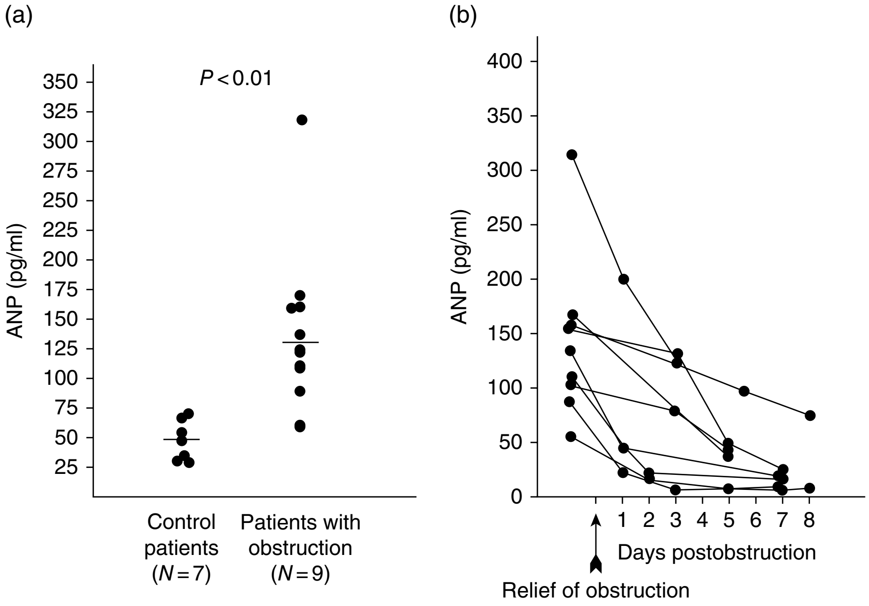

**Figure 8.6** Plasma ANP levels in (a) control group and patients with obstruction, and (b) before and after relief of obstruction. Reproduced with permission of Elsevier.

This natriuresis and diuresis was associated with an elevation of serum ANP in all patients, which decreased as water and salt excretion decreased (Figure 8.6). Because ANP is a known diuretic and natriuretic, it may be one of the main factors causing the loss of water and salt in the postobstructive state.

## Fibrosis in ureteral obstruction

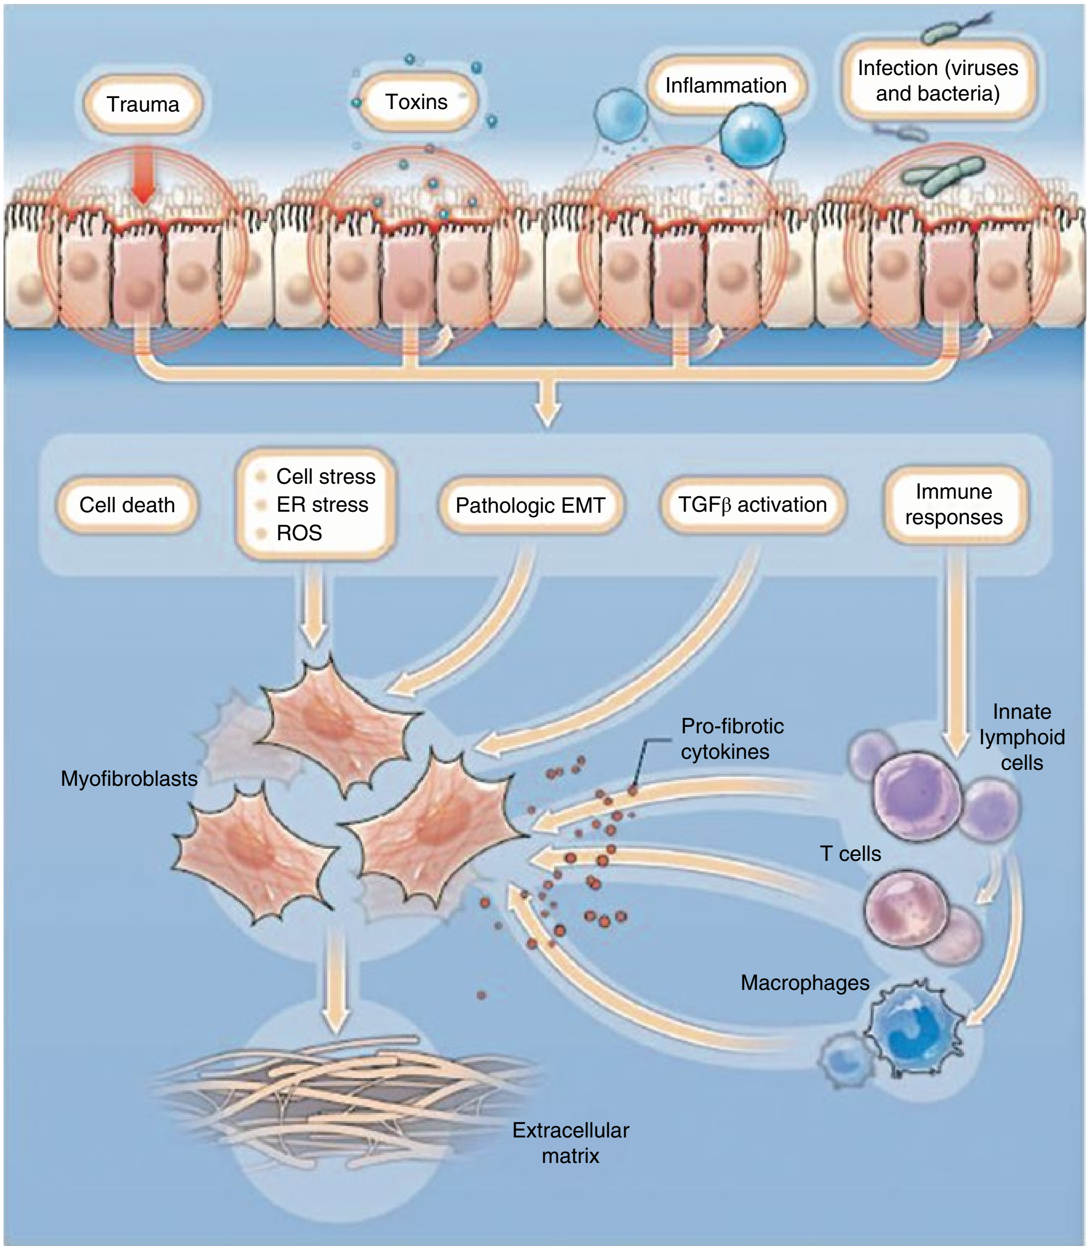
The obstructed kidney is characterized by accumulation of collagen-rich scar tissue, the most common feature of fibrotic organs. Most of the microscopic changes are confined to the tubules with little effect on the glomeruli. Fibrosis is a rapid occurrence in the experimentally obstructed kidney, with studies demonstrating the accumulation of collagens I, III, and IV, fibronectin, and laminin in the interstitium [63–65].

Despite the relative sparing of the glomerulus from fibrosis, there is a clear decline in GFR in the obstructed kidney. This is consistent with the finding in a variety of chronic renal diseases, that the presence of interstitial fibrosis is a major determinant of GFR [66]. There are several possible reasons for this: tubular atrophy can result in atubular glomeruli, which detached from their corresponding proximal tubules, are unable to filter properly [67]. The accumulation of extracellular matrix can isolate tubules from their oxygen supply and may also result in obliteration of peritubular capillaries, which can also result in decreased GFR [68].

Fibrosis is a complex process, and the mechanisms which initiate and sustain it are both the subject of much investigation and controversy. As more is understood about this process, the prospect of developing targeted therapies to attenuate this process becomes likely. Both the renal epithelium and fibroblasts have long been studied in the obstructed kidney. A review of fibrosis [69] presented five different ways in which epithelial injury can result in tissue fibrosis (Figure 8.7). The first is epithelial cell death, either apoptosis or necrosis. The second is dysregulation of metabolic pathways, resulting in cell stress. The third is epithelial-mesenchymal transition (EMT), in which there is a decreased expression of important epithelial surface proteins. The fourth involves interactions between the profibrotic cytokine transforming growth factor-β (TGF-β) and integrins, proteins that function mechanically by attaching the cell cytoskeleton to the extracellular matrix. And finally, injured epithelial cells initiate innate and adaptive immune responses. Each of these processes has been studied in the UUO model, and a summary of the most pertinent data is presented below.

### Tubular apoptosis

Truong et al. provided the first detailed analysis of apoptosis in UUO [70]. They studied the tubular and interstitial components from 0 to 90 days of UUO. There was virtually no change in glomerular apoptosis throughout the period examined. There was a sharp peak in tubular apoptosis at day 25, whereas interstitial apoptosis peaked at day 75. The apoptotic rate was twofold higher in tubular cells than in interstitial cells. Choi et al. demonstrated similar findings in mice studied from 4 to 45 days of



Trauma
Toxins
Inflammation
Infection (viruses and bacteria)
Cell death
Cell stress
ER stress
ROS
Pathologic EMT
TGFβ activation
Immune responses
Myofibroblasts
Pro-fibrotic cytokines
Innate lymphoid cells
T cells
Macrophages
Extracellular matrix

**Figure 8.7** Mechanisms by which epithelial injury can lead to organ fibrosis. A wide range of injurious stimuli initiate several distinct profibrotic programs in epithelial cells. In the most extreme case, injury induces cell death, which is sufficient to initiate fibrosis in a variety of fibrotic disease models. Injured epithelial cells can undergo dysregulated metabolism, leading to production of reactive oxygen species (ROS) and endoplasmic reticulum (ER) stress, or they can be reprogrammed toward a mesenchymal-like phenotype (pathologic EMT). In response to danger signals that are released or activated in response to injury, epithelial cells use cell-surface integrins to activate latent TGF-β, a well-characterized central mediator of tissue fibrosis. Finally, injured epithelial cells recruit and activate a variety of immune cells, which, in turn release profibrotic cytokines along with innate lymphoid cells, T cells, and macrophages (for example interleukins IL-13 and IL-17 among many others). Each of these perturbations of epithelial cells ultimately leads to expansion, recruitment, and/or activation of tissue myofibroblasts, the principal source of pathologic extracellular matrix that characterizes organ fibrosis.

UUO [71]. Tubular apoptosis was maximal at day 15, whereas interstitial apoptosis was still increasing at day 45. Docherty et al. suggested that tubular apoptosis is a major contributor to fibrosis in UUO, and conversely that inhibiting apoptosis decreases fibrosis in UUO [72]. In many experimental studies demonstrating effectiveness of various antifibrotic strategies tubular apoptosis was decreased along with decreases in fibrosis. However, whether this is causative or merely a response to the treatments remains to be determined.

### Dysregulation of metabolic processes and changes in cellular metabolism

Tissue injury can lead to disruption of the local environment. The cell stress response involves mechanisms by which cells cope with these disruptions. A significant participant in the stress response is the endoplasmic reticulum (ER), the cell organelle responsible for synthesis, folding, modification, and assembly of proteins. Although ER stress [73] can function to re-establish the normal environment, excess ER stress can damage cells, perhaps through inducing cell apoptosis and release of inflammatory mediators. Recent studies targeting different proteins involved in the ER stress response implicate this process in fibrosis. Metformin reduced renal fibrosis in UUO, along with expression of GRP78, a modulator of ER stress [74]. The reticulon family of proteins has been shown to be involved in apoptosis and the ER stress response. Reticulon 1 was found to be increased in UUO, and reduction of reticulon 1A expression in UUO both attenuated fibrosis and decreased ER stress markers [75].

ATP, the source of cellular energy, is made in mitochondria via the electron transport chain. Injury and aging may be characterized by a decrease in cellular ATP. A new class of compounds, the SS-peptides, have been shown to be remarkably effective in decreasing and preventing tissue injury in response to a variety of insults [76]. SS-31, a prototype of this group, has been shown to interact with and stabilize cardiolipin in the inner mitochondrial membrane [77]. This prevents mitochondrial damage and maintains ATP levels. Mitochondrial dysfunction in UUO has been shown in studies demonstrating increased cytosolic cytochrome *c* [78]. Using the mitochondrial targeted SS-31 in UUO, we demonstrated its efficacy in deceasing fibrosis, apoptosis and oxidative stress [79].

### Epithelial-mesenchymal transition

*In vitro*, it has been shown that tubules can be transformed into cells with a myofibroblastic phenotype. Many studies have demonstrated that incubation of renal tubular epithelial cells with varying doses of the TGF-β causes changes [80, 81] including: (i) the typical cobblestone appearance of cells in culture is replaced by the elongated spindle shape associated with fibroblasts and (ii) loss of apical–basal polarity and cell surface microvilli: the apical–basal polarity is replaced by a front end/back end fibroblast-like polarity; (iii) using electron microscopy, large bundles of actin microfilaments and dense bodies are seen; (iv) the expression of either α-smooth muscle actin (α-SMA) or fibroblast-specific protein-1 (FSP-1); and (v) loss of the epithelial antigen, E-cadherin. The effects of TGF-β are blocked by a neutralizing antibody to TGF-β. The loss of cell adhesion, expression of the mesenchymal markers, and subsequent degradation of the basement membrane allows for changes in shape and motility. Many studies have demonstrated that epithelial-mesenchymal transition (EMT) occurs in UUO and have suggested that this is a major contributor to fibrosis. Yang and Liu showed a marked decrease in E-cadherin and a marked increase in α- SMA in UUO [82]. There was also an increase in TGF-β receptors in renal tubules. When hepatocyte growth factor was administered, interstitial fibrosis was decreased, as well as the expression of α-SMA. Iwano et al. used a combination of bone marrow chimeras and transgenic reporter mice, and studied the expression of FSP+ cells in UUO [83]. They determined that a small population of FSP+ cells derived from bone marrow, but a larger proportion arose from local EMT of proximal tubular cells. Both FSP+ cell populations were able to synthesize collagen and to proliferate. Conversely, when they used methods to selectively remove the FSP+ cell population in the kidney and the mice then underwent UUO, both type I collagen deposition and fibrosis were reduced. These results demonstrate that FSP+ fibroblasts are at least partially responsible for the fibrosis of UUO [83]. Sato et al. have also demonstrated decreased E-cadherin and increased α-SMA expression in UUO [84]. Using Smad-3 knockouts (a downstream effector of TGF-β), they demonstrated that the decrease in E-cadherin and the increase in α-SMA can be reversed. Furthermore, Smad-3 knockouts exhibit less fibrosis than their wild-type counterparts. In a recent review of the role of EMT in fibrosis, Zeisberg [85] notes that, in mice, transgenic expression of snail, a protein induced in epithelial cells by EMT, recapitulates all stages of renal fibrosis in mice. Despite all the previous studies, there has recently emerged evidence that challenges the role of EMT; this has been reviewed recently by Duffield [85, 86], who suggests that some of the data implicating EMT represent artifacts and have therefore led to erroneous conclusions. One study used fate mapping of mesenchyme-derived stromal cells of the developing kidney that mature into perivascular pericytes (perivascular cells that wrap around blood capillaries) in the adult kidney; this study showed that pericyte precursors are the primary and only source of myofibroblasts in the UUO model [87]. The other used an epithelial-specific transgene Ksp-Cadherin-Cre to activate the heritable marker yellow fluorescent protein (YFP). In the UUO model, the authors detected neither epithelial cells that migrated out of the epithelial compartment nor any epithelial cells that became myofibroblasts [88].

### Interactions of TGF-β and integrins

TGF-β has long been implicated in the fibrosis of UUO. Studies from our laboratory as early as 2000 demonstrated that 1D11, a monoclonal antibody to TGF-β, decreased fibrosis, apoptosis, and macrophage infiltration in UUO [89]. Similar results were found with antisense to TGF-β [90]. Subsequently many other studies confirmed these findings using other strategies to decrease fibrosis [1, 2, 91]. TGF-β exists as a latent form, and when epithelial cells contract, bound integrins lead to local TGF-β activation, potentially at a high local concentration [92]. This could lead to EMT, as described above, or to activation of other cells in the vicinity, including fibroblasts. Interestingly, inducible deletion of the TGF-β type II receptor in matrix-producing interstitial cells in the UUO model did not abrogate fibrosis in the UUO model; thus, despite showing decreased collagen in interstitial cells which were of mesenchymal origin, fibrosis was not affected. Thus, although TGF-β is clearly an important mediator in UUO, other cytokines may be able to replace it in its absence [93].

### Activation of immune responses

Secretion of inflammatory cytokines from epithelial cells leads to the recruitment of different immune cells into the local environment. In UUO, the macrophage has been studied most thoroughly. As early as 1994, an increase in macrophages in interstitial tissue by 12 hours after UUO was demonstrated [94]. There was a continued increase through 96 hours. We and others have confirmed the presence of interstitial macrophages in UUO [65, 95, 96]. Recent attention has focused on macrophage sub-types in UUO. The two broad sub-categories of macrophages are M1 (activation associated with inflammation) and M2 (dampen inflammation; reviewed in [97]). An early increase in expression of M1 macrophages was shown by Tian et al. [98], in association with high-mobility group box 1 protein. Markers for both M1 and M2 macrophages were upregulated in a vitamin D3 model of increased fibrosis in UUO [99]. Several inflammatory cytokines have also been studied. Both interleukins IL-18 and IL-1β have been shown to be upregulated in the UUO model [100, 101]; neutralization of IL-18 reduces interstitial fibrosis [101]. Interestingly, a recent study using the SS-31 peptide (see above) in a renal ischemia/reperfusion model, has shown its effectiveness in preserving mitochondrial integrity, ameliorating expression of inflammatory markers (including IL-18 and IL-1β) and halting progression of interstitial fibrosis; this was remarkable, considering that SS-31 was administered 1 month after the initial ischemic insult [102]. Activation of IL-1β and IL-18 is under the control of immune receptors which form large multiprotein signaling complexes, known as inflammasomes [103]. Since mitochondria play an integral role in the assembly and activation of the inflammasome, Szeto and colleagues suggest that protection of mitochondria during ischemia and inflammation results in reduced inflammation and fibrosis.

### Strategies to decrease fibrosis

Over the last 30 years, investigators have attempted to decrease the fibrosis of UUO through either drug treatments or genetic manipulation. Many of these have targeted single mediators (TGF-β or angiotensin II for example), which had been implicated in the fibrosis of UUO (for reviews see [1, 2, 91]). However, virtually none of the treatments aimed at a single target have produced treatments ready for use in patients. Our recent understanding of the complexity of the fibrotic process suggests that while there are new pathways to target, the multiple factors responsible for fibrosis may lead to strategies requiring intervention in more than one pathway. Alternatively, protection of mitochondria, which has been shown to prevent acute and chronic injury in several models [76, 102], may prove to be a unique and effective antifibrotic strategy.

# Organizing the Endourological Operating Room

*Ravindra B. Sabnis, Abhishek Singh, & Shashikant Mishra*

*Department of Urology, Muljibhai Patel Urological Hospital, Nadiad, Gujarat, India*

## Introduction

To work effectively an operating room (OR) needs specialized planning and execution. A combined "civil–mechanical–electrical–electronic–biomedical" effort is required, coordinated by the needs, preferences, and safety of the medical/surgical team. Apart from the scarcity of practical publications and details in this area, the highly technical nature of many of the issues, and the difficulty of communicating them, often result in planning mistakes being made at a very simple level.

OR complexes are designed and built to carry out investigative, diagnostic, therapeutic, and palliative procedures of varying degrees of invasiveness. Since the introduction and widespread application of minimally invasive surgery, the design of the modern OR has changed dramatically. Adapting the modern OR for endourology is a challenge that begins with the more general problem of designing the OR. There is a need for safety, convenience, and economy in planning a dedicated endourology fluoroscopy-compatible OR complex. It is necessary that planning is perfect, keeping in mind future needs, as subsequent changes or renovations are tedious and pose tremendous economic burden [1].

In the current era of information technology, audiovisual (AV) recording and telementoring have become a frequently used teaching and training aid in operative surgery (see Chapter 3 in this volume). Most surgical meetings today devote a major session to the live operative workshop. Unfortunately, many video recordings are of poor quality and often, because of the constraints of the equipment and the operating environment, do not demonstrate the principles of the technique as well as the presenter intended. The other problem is economic restriction, especially in semi-government-aided or private hospitals. These shortcomings are severely felt, especially in a tertiary care teaching hospital, as surgical workshops are held quite regularly and AV transmission consumes a large chunk of the investment. In addition to being used to relay the operation, the teacher can access the video display to monitor the progress of the operation, and it can be used to teach residents in the OR about the procedure.

In this chapter we present a comprehensive description of the planning of a state-of-the-art endourology-dedicated OR, with both high-class OR equipment and technology-driven OR data management.

## Designing and planning a dedicated OR

The design and layout of the OR is extremely important. The state-of-the-art design enables hassle-free movement of equipment, surgeon ease in viewing multiple screens, and efficient data archiving, management, and relay systems. It is necessary to anticipate the average number of procedures that will be carried out. It is better to plan with the next 10 years in mind.

Meeting these challenges requires a multidisciplinary team and a well-planned process that addresses all aspects from long-term goals to exacting details. Design and construction firms apply experience and expertise to handle the intricacies of the dedicated OR. Select an architect and construction manager with considerable healthcare experience, including of surgical suites and ORs. Architect, engineer, equipment planner, construction manager, and key equipment vendors should all be included in the team [2]. Strategic equipment placement is essential to increase efficiency and safety within the surgical space. Equipment booms and other ceiling- supported equipment are used increasingly in ORs because of the advantages they offer [3]. Equipment booms are ceiling-mounted, articulated arms that support much of the OR equipment, like

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

lithotripters, light sources, endocameras, electrocautery equipment, anesthetic gas connections, and electric plug points. The booms, which can move in every direction, significantly reduce clutter and interconnect equipment, freeing floor space and simplifying cleaning. They utilize the space above the false ceiling, thereby enhancing sterile setup and reducing maintenance as a result of cable breakage. Booms, however, require a significant amount of structural support, which must be coordinated with the lighting, mechanical, and electrical systems above the false ceiling.

## General principles of OR construction

In general any OR is divided into four zones:

Zone 1. Protective zone: the administrative area of the OR that houses changing rooms, store and record rooms, etc.
Zone 2. Clean area: such as pre- and postoperative rooms
Zone 3. Sterile area: OR, anesthesia room, scrub room
Zone 4. Disposal area: housing waste from all the ORs.

The OR should have a unidirectional flow of movement: there should be one entry and one exit. Pre- and postoperative rooms should be separate. There should be no toilets in the clean area. Scrub room should be in between the ORs. ORs should have automatic sliding doors or double swing doors with a vision panel. ORs should have one door for patient entry and another for surgeons' entry from scrub room. The OR should have 30 air changes per hour, a positive pressure of 15 Pa, a temperature of 21 ± 3 °C degrees, and a relative humidity of 55%.

## General design for a fluoroscopy-compatible endoscopic OR

### Size

The size of a general OR should be a floor area of 6 × 6 m with a height of 3 m. Since endourologic procedures use large equipment, like a C-arm, laser, ultrasound machine, and workstation, the recommended size of a dedicated endoscopic OR is 7 × 7 × 3.5 m.

### Ceiling

The floor-to-false-ceiling height should be around 3.5 m. The overall height of the OR should be around 4.2 m to give an over-ceiling space of 70 cm. Individual cassettes made of painted sheet steel are clipped into the grid to form a suspended metal ceiling. The individual cassettes can be removed and reinstalled to permit maintenance and refitting work.

The over-ceiling plan is an important feature. This space includes:

- Cables for various multiple equipment booms, such as oxygen, nitrous oxide, compressed air, vacuum, and electrical wires.
- Air conditioning pipelines.
- Data-relay wires in various hanging arms.

The ceiling air supply with a sterile-air distributor is one of the most important elements for hygiene in the OR. Bacteria, viruses, and dust particles are trapped immediately before the air enters the room. The sterile-air distributor generates a homogenous and low-turbulence displacement flow. The inner air supply area remains free from contaminants drawn in from the room environment. In this way the area around the operating table is kept in a high state of cleanliness during operations, with an extremely low pathogen level of less than 10 colony-forming units per cubic meter. Sterile-air distributors can be easily detached or swung away for quick and economic filter changes.

### Pendant services

Two ceiling pendants for pipeline services should be designed: one for the surgical team and one for the anesthesiologist. The anesthetic pendant should be retractable, have limited lateral movement, and provide a shelf for monitoring equipment. It should have oxygen, nitrous oxide, and 4 bar medical compressed air, medical vacuum, scavenging terminal outlets, and at least four electrical sockets. The surgeon pendent or cart should have the capacity to hold video camera electronics, a light source, and various recording devices such as a VCR, printer, or videodisc recorder. Moreover, some carts also have room to hold the laparoscopic insufflator and electrocautery units.

### Floor

OR flooring should be made of 2 mm-thick antistatic PVC roll/tile/epoxy coating. The floor should have a slight tilt from all the walls, converging at the water drain outlet. The floor surface must be slip resistant, strong, and impervious, with minimum joints; e.g. mosaic with copper plates for antistatic effect or jointless conductive tiles/terrazzo, linoleum etc. The recommended minimum conductivity is 1 mOhm with a maximum of 10 mOhm There should be a central drain outlet from the floor, centered underneath the OR table. A 0.05 × 50 mm copper grounding strip should be used for earthing and one lead should be brought out for every 45 $m^2$ area.

## Walls

The radiation protection of a general-purpose fluoroscopy suite necessitates a wall thickness in all directions equivalent to 2 mm of lead (15 cm of concrete or 25 cm of brick with plaster). While lead is always accepted as the standard material for radiation protection, ordinary building materials may be equally suitable provided they are thick enough. As for the floor, the surface of the walls must be slip-resistant, strong, and impervious, with minimum joints. Laminated polyester or smooth paint provides a seamless wall surface; tiles can break and epoxy paint can chip. Washable paint in a light color (off-white, light blue, or green) is ideal. There should be provision for an X-ray film illuminator, wall-mounted camera, plasma screen, and drawers for endoscopic disposables recessed into the wall.

## Main door

The main door to the OR must be of adequate width (1.2–1.5 m) to facilitate smooth patient trolley, laser, C-arm unit, and ultrasonography machine entry and exit. Sliding doors are preferred, as they do not generate air currents. Door opening can be both automatic, with laser control, and manual.

## Lighting

Different levels of lighting are necessary in the OR and a means of dimming light may be needed during endoscopic procedures. A flat TFT monitor display for endocamera vision requires the installation of dimmable lighting to create optimum light levels. However, TFT monitors are now being replaced by HD monitors, which may not need dimmable lights. Color-corrected fluorescent lamps are preferred to produce even illumination of at least 500 Lux at working height, with minimal glare. In the operating area, overhead light should be shadowless and give 25 000–125 000 Lux of light (50 000–100 000 Lux at the center and at least 15 000 Lux at the periphery), as in the general OR. Light-emitting diode (LED) light provides a unique multicolor temperature facility, which proves helpful during open surgery, and may be required in the event of an endoscopic complication. LED light has the advantage of lower heat generation, adjustable light characteristics, and unlimited lifespan. Lights should be freely movable in both the horizontal and vertical planes, and for this movement equipment booms are generally preferred.

## OR table

The OR should have a mobile, modular operating table with electronically controlled hydraulic drive, and battery and mains operation, and be of adequate width and weight-bearing capacity. It should have a stable base construction with a rotatable top and large twin-disk castors for easy maneuverability. The operating tabletop needs to be subdivided into multiple sections: head plate, upper back plate, lower back plate, seat plate, and leg plates for lithotomy position. To be compatible with fluoroscopy, the entire tabletop should be devoid of cross bars. Provision for kidney bridge elevation is helpful if open exploration is required. There should be multilayered radiolucent foam padding for patient comfort and safety.

## C-arm

A mobile C-arm unit is essential in an OR dedicated to urology. It should have balanced and graduated movements at any angle. It should provide a high-quality image to allow quick and precise diagnosis (brightness should be monitored so that image quality is not affected by changing lighting environments). Functions of the image intensifier should include DICOM imaging capabilities, last-image hold memory, image processing, and text/graphics. Image display should be on a high- resolution TFT monitor. The data output from the C-arm may also be connected to one of the hanging screen monitors for easy viewing by the operating surgeon. Traditionally C-arm units like the Surgico 60 DHF™ (PHILIPS, India), a digitalized mobile surgical C-arm image intensifier system, are used. It is an electronically controlled unit with a C-arm stand, X-ray generator and image intensifier, charge-coupled device (CCD) camera, monitor with trolley and image memory. The voltage can be adjusted with a range of 40–100 kV with automatic cutoff at 100 kV, when the machine shuts off. The current (milliampere) readings can also be varied, but the display will not show millamps until and unless the exposure switch is pressed. The fluoroscopy timer displays the exposure time with a preset reading of 300 seconds. Once this is reached, the machine will give an overload indication and no exposure will be obtained unless the timer is reset to 0.

Now a new range of C-arms with high-frequency, powerful generators operating with a variable pulse width between 7 and 30 ms are available. They are monoblock generators with a rotating anode. These machines deliver short, sharp pulses, which minimizes dose exposure and maximizes image quality. Newer machines have automatic pulse regulation that helps in continuous imaging. They have an active cooling system, which keeps the generator temperature low and prevents overheating of the unit. Radiation exposure is an important aspect to be considered. The principles of as low as reasonably achievable (ALARA) should be followed.

Collimation, adjustment of frame speed, should be available to reduce radiation. Manual adjustment of current and voltage reduces radiation exposure more than keeping the machine on auto mode.

## High-definition camera systems

Laparoscopic and endoscopic camera heads consist of a coupler and a CCD. Single-chip cameras have a single CCD. The coupler links the camera with the lens and can be used for focusing. The optical zoom feature adjusts the image size and magnification. Three-chip cameras have three CCDs; here, each chip is responsible for reproduction of a single color and it produces more natural colors.

There are two types of camera: standard definition (SD) and high definition HD. These are defined by horizontal and vertical resolution. The SD camera had an aspect ratio of 4:3 and a resolution of 640 × 480 horizontal and vertical lines. As compared to SD, HD cameras have an aspect ratio of 16:9 and 1280 × 720 horizontal and vertical lines. The 1080 HD systems offer an aspect ratio of 16:9 and 1920 × 1080 horizontal by vertical lines: this is almost seven times the resolution of an SD system.

The other two important features about camera systems are temporal resolution and scanning. Temporal resolution is the number of captured images per unit time expressed as frames per second. Scanning is of two types. In progressive scanning the whole frame is captured as you image. The other type of scanning is interlaced scanning in which two fields of half images are combined to produce a single image. Progressive scanning offers twice the temporal resolution compared to interlaced scanning. The scanning type can be identified by the suffix “p” or “i,” e.g. 720p or 1080i. Presently 1080p is one of the highest standards of HD cameras available for laparoscopic surgery. Using these new systems, vision is so good that the anatomical structures that were not seen with a flat SD image now become clearly visible.

Setting up a camera in the OR should include covering it with a camera cover; if the camera is sterilizable it can be used without a cover. A light source must be connected and the camera should be white-balanced. White balancing is a digital phenomenon in which the camera counters any impurities of color. This means that if any particular color has a higher level in the image, say the color blue, then the other two colors are increased in proportion, in this case red and green, to make the white areas of the image appear white. After white balancing the camera should be focused, at which point it is ready to be used.

## Sterilization

There should be a separate room for cleaning and disinfection of endoscopic instruments, which should have adequate ventilation to remove toxic vapors and airborne pathogens (see also Chapter 1). Automated disinfection machines for endoscopic instruments are desirable. However, there should also be provision for manual rinsing and cleaning. If endoscopes and other accessories cannot be autoclaved, there needs to be provision for chemical sterilization and ethylene oxide. Endoscopic procedures need delicate and expensive equipment, like telescopes, flexible ureteroscopes, and flexible nephroscopes. Rapid sterilization is required if many procedures are to be performed in a day, and for this we recommend a Sterrad sterilization system close to the OR, which provides a high level of sterilization with a processing time of half an hour.

## OR configuration for endourologic procedures

The configuration of an endourology OR is different from that of a general OR, as equipment has to be strategically located. This will minimize procedural time by allowing intuitive control and shorter changeover times, as equipment settings can be freely defined and activated. The OR should integrate cameras, lights, video conferencing units, endoscopic and anesthetic equipment, the C-arm, and the operating table, and all should be capable of being operated from the sterile area. The anesthetic trolley should be on a mobile cart supported by the anesthesiologist’s equipment boom, and located at the cephalad end of the patient on the same side as the procedure. There should be a minimum of three hanging display screen monitors, supported by a boom, moveable in all directions, and placed in front of the surgeon (Figures 9.1 and 9.2). The display monitors should be interconnected with changeable viewing between fluoroscopic image, endovision image, ultrasound image, and hospital information management system (HIMS) image.

Quite often both kidneys need to be operated on under the same anesthesia. This can be done in two ways. In the first, the C-arm unit remains fixed while the anesthesia boom and table rotate through 180°. In the second, the anesthesia trolley and table remain fixed while the surgeon’s position changes. Display screens accordingly also change the direction in which they face. The light cable source, lithotripsy device, endocamera cable, and irrigation tubing are attached to the equipment boom on the right side behind the surgeon.

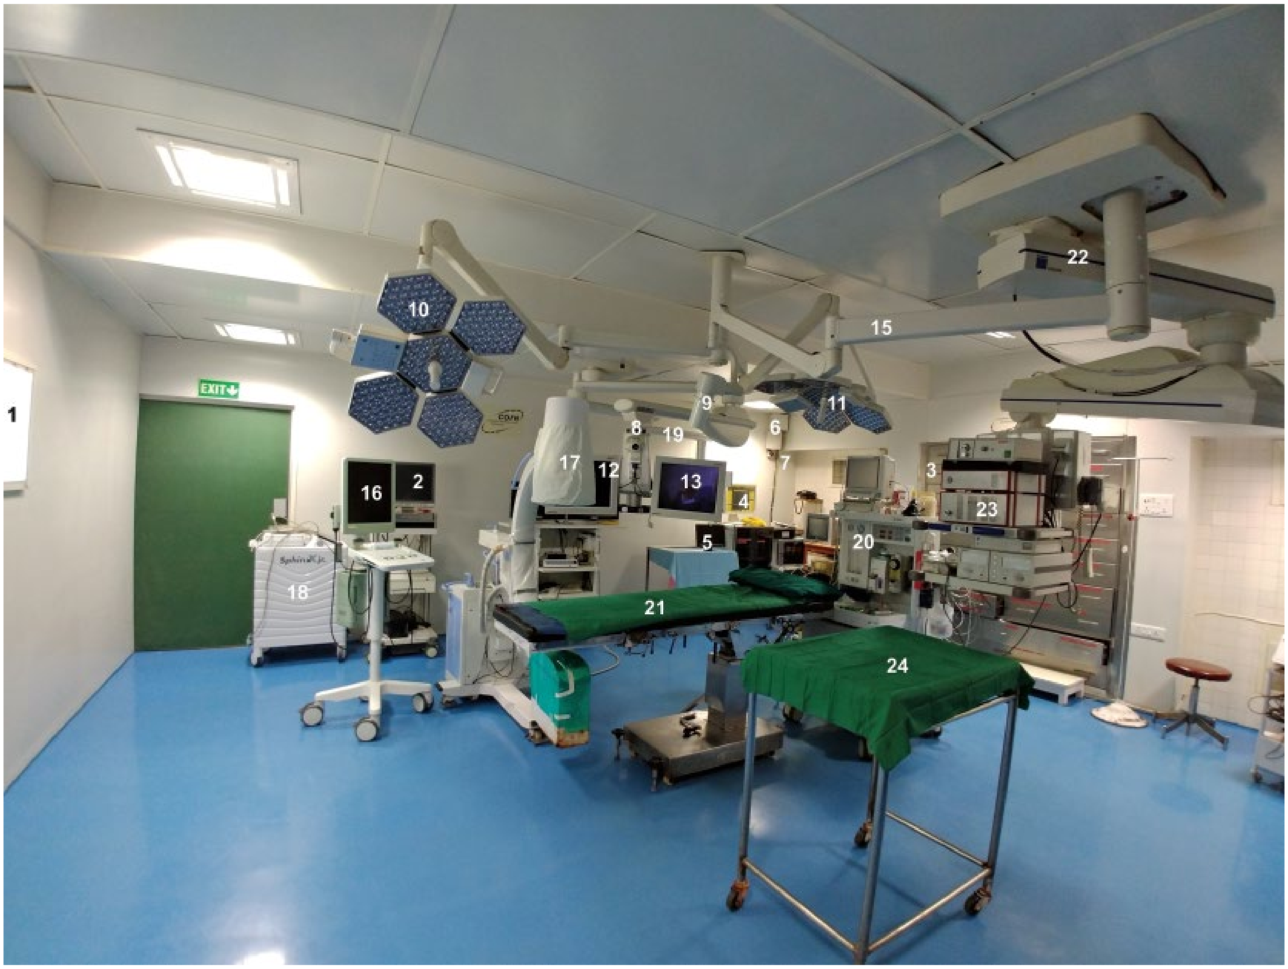

**Figure 9.1** Surface view of a dedicated fluoroscopy-compatable endourology OR. For explanation of numbers, please see the key to Figure 9.2. Reproduced with permission of Mary Ann Liebert, Inc. Publishers.

Figure 9.2a shows the essentials of a strategic equipment setup for left percutaneous nephrolithotomy (PCNL).

### Principles of OR room set up for ureteroscopy

The OR design should be as described earlier in chapter and the OR table should be fluoroscopy-compatible. The patient is positioned in the lithotomy position with both the limbs resting on lithotomy stirrups or Allen's stirrups (Figure 9.2b). Limbs should be well padded and all pressure points should be well secured. Special care should be taken to prevent pressure onto the lateral aspect of knee to prevent damage to the common peroneal nerve. The surgeon stands at the foot end; anesthesiologist and anesthesia cart are at the head end. The surgical assistant and the scrub nurse stand to the right of the surgeon. The C-arm fluoroscopy unit should be positioned across the abdomen and should be able to move from xiphisternum to pubic symphysis. For a right-sided procedure the C-arm should be placed on the right side of the patient. The endovision screen should be facing towards the surgeon. There should be another endovision screen for the assistant; this screen can be placed on the camera cart. The distance between the screen and surgeon should be equal to five times the diagonal dimension of the screen. The camera, light source, and energy source (except laser) can be mounted on a trolley or cart and should be positioned on to the side opposite to the C-arm. Whenever laser is used it should positioned opposite the side on which the C-arm is kept. The irrigation fluid can be mounted on a stand and kept at the foot end of the patient on either side.

### Principles of OR room set up for PCNL

Here we describe an OR arrangement during a PCNL procedure done in prone position (Figure 9.2c). The general design of an OR for PCNL remains the same as described elsewhere in this chapter. The OR table should be compatible with fluoroscopy and should have attachments for

lithotomy stirrups. For a right-sided PCNL, which is being done in prone position, the anesthesiologist and anesthesia trolley are positioned at the head end. The patient is positioned in prone position with two bolsters placed below the lower chest and hips. The operating surgeon stands on the side to be operated, i.e. on the right side for a right-sided PCNL. The surgical assistant stands to the left of the surgeon and the scrub nurse should stand to the right of the surgeon. The C-arm and the ultrasound machine are positioned opposite to the surgeon, with their respective screens facing the surgeon. Two endovision screens, one on either side of the C-arm, face the surgeon. The camera unit, light source, and energy source are placed on a boom/pendant/cart behind the surgeon. The laser machine is also placed behind the surgeon. All the lines should be tangle-free and the irrigation fluid is mounted on a stand and placed at the foot end of the patient.

## Principles of OR room set up for upper genitourinary tract laparoscopic surgery

While planning the OR room setup for laparoscopy one should keep in mind that the surgeon should always be optically correct, which means that their eyes, the organ of interest, and screen should be in the same line (Figure 9.2d). The distance between the monitor and the surgeon should be equal to five times the diagonal of the screen. The level of the screen should be 15° below the level of eyes so that there is no strain on the neck muscles. The OR table should be adjustable to 24 cm from the ground, which will be approximately the level of the waist of the operating surgeon. The height of the operating table should be equal to 0.49 times the height of the surgeon. For upper genitourinary tract surgery the patient should be in a lateral position with the ipsilateral side up and on the ipsilateral edge of the table. All pressure points should be secured. The anesthesiologist is at the head end and the surgeon stands on the ipsilateral side of the patient. The camera driver stands cranial to the operating surgeon; the scrub nurse stands at the foot end with the second assistant stand on the contralateral side. One screen is placed in front of the operating surgeon and the other screen is placed behind for the second assistant to see. The camera, light source, $CO_2$ insufflator, electrosurgical units, and various other light sources are kept in front of the surgeon on a vision cart/boom/pendant.

### Principles of OR set up for robotic surgery

The OR should be spacious, as stated earlier in the chapter (Figure 9.2e). Robotic systems have three components, each of which is at least 60 cm in width. In addition to this, the robotic OR is also the laparoscopic OR in most institutions. Considering the above, the size of the robotic OR should be 7.6 × 7.6 × 4 m. All the cable connections between the three robotic carts should be tension- and tangle-free. There should be enough space in the OR to facilitate robotic docking and for hassle-free movement of OR personnel.

The OR table, patient, and vision cart should be clearly visible to the operating surgeon from the console. The vision cart can be used to place $CO_2$ insufflators and electrosurgical units. Additionally, a laparoscopic tower can be used to place the $CO_2$ insufflator, electrosurgical units, and laparoscopic light source.

The type of surgery will determine the robotic OR setup. In case of a pelvic surgery, depending on unit policy the patient-side surgeon, second assistant, and scrub nurse will stand on either the left or right of the patient. We prefer that the patient-side surgeon and other surgical assistants stand on the left of the patient. This also means that the vision cart will be on the right of the patient. The patient-side surgeon has two monitors to view: the first is on the right of the patient and the other is towards the foot end of the patient, which is either wall- or ceiling-mounted. It is preferable to have a three-dimensional monitor as it will give a similar view to the bedside surgeon and the console surgeon. The patient-side surgeon should preferably use the screen at the foot end of the patient as to be coaxially aligned with this screen. The anesthesiologist and the anesthesia cart are at the head end of the patient and should be 60 m away from the patient's head end; this gives working space to the bedside surgeon. All the intravenous lines and tubing should have an extension. If the surgical assistants stand to the right of the patient the OR setup will be a mirror image of the one described above.

For the upper genitourinary tract surgery, the position of the anesthesiologist and console surgeon remain the same. For right-sided upper tract surgery, the patient-side surgeon stands on left of the patient and the vision cart with $CO_2$ insufflator and electrosurgical units are placed to the right of the patient. The patient-side surgeon views a screen placed to the right of patient and is coaxially aligned with the same. For left-sided upper tract surgery a mirror-image setup of the one described above should be used.

## Modular operating theatres

The prefabricated modular operating theatre offers the advantage of speedy construction combined with design of the highest quality and standards, while allowing for future expansion and development in surgical technique. The standard package includes an operating table, operating lights, endoscopy equipment, and a range of monitors that surround the patient [4].

Two dedicated endourology modular ORs are currently available, one from Karl Storz (Karl Storz OR1™; Karl Storz, Tuttilingen, Germany) and the other from Richard Wolf GmBH (Core™), which can be installed on demand by the respective technical teams. The Karl Storz OR1 provides the modular OR layout for performing minimally invasive endourologic and laparoscopic procedures. Key features include optimal picture quality from various camera systems and other signal sources, integration of Karl Storz endoscopic equipment, the full range of functions of devices and peripheral systems made by other manufacturers, such as the OR table and room lighting, and simple and secure documentation of intraoperative recordings and the OR environment at a central location. Core has a modular, networked structure to link various devices in the operating theatre. The system provides interactive monitoring and centralized control from a single operator panel, and has speaker-independent voice control that enables devices such as cameras, lights, video conferencing units, image archiving systems (PACS), high-frequency equipment, room functions, and the operating table to be operated from the sterile area. Medimage, a digital patient imaging and document management system, facilitates intraoperative visualization of preoperative image data on monitors located within the operating area.

### Integrated surgical data-acquisition systems

Documentation is a very important part of surgical management of patient. It is of a great medicolegal value as in a court of law anything that is not documented has not been done. Traditionally all the data acquisition was done by using multiple recorders: one for the endoscopic camera, one for ultrasound, one for the C-arm, and one for the surface camera. Then came the central workstations with inputs from different sources. Video was recorded in one unit but simultaneous recording was not possible and it was a device only used for recording.

We now have integrated documentation systems, which capture patient data, procedure data, images, and video. These systems are in turn connected to hospital information system so that this data can be accessed from anywhere in the hospital. These modern systems have a central control unit (Figure 9.3a), which has facilities patient data entry; surgical checklists can also be incorporated into them. The OR lights, electrosurgical units, and various screens in the OR can be controlled through one workstation (Figure 9.3b). In addition, the same system helps in video recording (Figure 9.3c), editing, and video relaying. There are a few data acquisition systems on the market:

1) Advanced Image and Data Acquisition (AIDA)™ (Karl Storz). AIDA can be integrated with the existing hospital information system. The patient information has to be put in manually or using a DICOM work list. The preoperative checklist (Figure 9.3c) can be incorporated into the system and can be followed up as per institutional protocol. Once this is done recording can be started; video recording as well as still image capture is possible. Recording can be done in full HD and three dimensions. There is also an option of multiple capture, i.e recording from different independent sources simultaneously, e.g video from the C-arm and endovision camera can be simultaneously recorded. Editing a video is also possible, and still images can also be used to generate reports. AIDA can be interlinked with STORZ communication bus (SCB), enabling communication with other devices like the $CO_2$ insufflator, light source, and electrosurgical units. All of these devices can be operated centrally using this system.
2) ENDOALPHA™ (Olympus Surgical, Orangeburg, NY, USA). The ENDOALPHA system by Olympus is a system that integrates surgical systems, allows central control of medical equipment like endoscopic equipment, surgical lamps, video management equipment, room lights, operation table, etc. All this equipment can be controlled via a touch screen or by voice commands. The settings as per requirement of the surgical team at different stages of the surgery can be stored and can be reproduced at a particular stage of surgery.

(d) The central integration units can be controlled by remote, wireless headsets, touch screen, and a laparoscopic camera head.

For example, while gaining access to the calyx one needs the OR lights on, so that surgeon can see the point of entry of needle on the skin. Once the surgeon starts doing nephroscopy the OR lights need to be dimmed. Normally all this has to be done manually but in ORs with central integration systems it can be done from a central control or using voice commands. These measures improve the autonomy of operative team and also reduce the time between requests and the resultant action. Thus such systems enhance workflow and ergonomics in the OR. These systems also have a provision for documentation and can be connected to the hospital information system. The patient details can be filled in or imported from the hospital information system. As the procedure is started it can be recorded and simultaneously broadcasted live. For recording a central monitor with touch screen can be used. There is also a foot pedal control available for taking snapshots, and starting and stopping recording, which can be controlled by the surgeon. Once the recording is over, a report can be created in the form of images with comments. Video can be created and can be immediately transferred to the hospital information system.

3) SCD Information Management System™ (Stryker). This device has a capability of digital data capture, multiple device control, and data connectivity. There is a provision for patient data entry and surgical time-out and it is capable of full HD recording. The central control unit can be controlled remotely by touch screen, wireless headset, or by buttons on the camera head (Figure 9.3d). These features make it possible for the surgeon to use the device while operating. This system has a WiFi connection, allowing videos to be streamed live. Other features include being able to create surgeon profiles and storing the desired settings for a particular surgery.

## Data management

In the current era of information technology, data capture, archival, and relay have become a frequently used teaching and training aid in operative surgery [5] (see Chapter 3). The ability to project computer and video information to a class or auditorium is now almost essential in many tertiary care hospitals, driven by the exponential increase in computer usage by both teaching staff and students. This need for versatile, large-screen electronic display systems is the dominant factor influencing the design of AV facilities, and is typically the most expensive single equipment element of any presentation system. Other technologies have grown up around the electronic display capability, and the expectations of users have become more sophisticated.

### Data capture

A surgical video system (SVS) is an integration of components used to perform minimally invasive surgery. In the OR, an SVS consists of an endoscope, attached video camera, light source, video processor, and one or more video displays.

#### Endoscope

Digital videocystoscopy and ureterorenoscopy use high-resolution monochrome CCD chip technology [5]. Three-chip systems provide better overall image quality than one-chip systems. The use of HD cameras and monitors during minimally invasive procedures can provide the surgeon and operating team with more than twice the resolution of SD systems. If an HD camera is selected it is imperative to invest in computer hardware and software capable of editing and outputting HD video.

#### Video camera

There are many options for avoiding poor-quality video capture in surgical procedures on the body surface. The simplest and most cost-effective method in this setting is to employ a video camera mounted on a tripod (surface camera) or installed on the wall with movable pulley (overhead camera). These are available from any number of consumer electronics outlets and in a variety of formats. Although it is possible to obtain reasonable quality video recordings by using the automatic exposure settings on most cameras, this often requires diversion of the operating light away from the operative field to avoid overexposure of the image. Almost all cameras, however, will have a predefined setting for bright environments, and this is an ideal alternative to use in this situation.

#### Video light source

Additional advances in imaging have resulted from the use of high-intensity light sources, generated by either halogen or xenon sources. The ability to adjust light intensity using several mechanisms has been a recent advance. Newer CCDs or image sensor-based endoscopic cameras feature electronic exposure. Recent innovations in illumination technology use single- or multipoint shadow-inducing systems.

#### Video and image capture

When performing endourologic surgery, video capture is not usually an issue. A signal can be taken directly from the lineout plug of the camera-processing unit and inputted directly into an analog or digital VCR using an S-video connection. Some endoscopic video processors come equipped with digital video (DV) outputs, which capture HD video. Of importance in a dedicated OR is an efficient to-and-fro data capture for HIMS. HIMS uses a network of computers to gather, process, and retrieve patient care and administrative information for all hospital activities to satisfy the functional requirements of all those involved in the care of patients. It is also helpful to the hospital authorities for developing comprehensive healthcare policies. HIMS incorporates an integrated computerized clinical information system for improved hospital administration and patient healthcare. It also provides an accurate, electronically stored medical record of the patient. There are innumerable software packages currently available for installing HIMS as per local preferences. The software has to be installed on all computers in the OR complex. Separate hardware for HIMS exists which has outputs for S-video and composite video. The output is connected to the OR panel and through it to the various data-capturing units working during the procedure. In this way, multiple images and videos can be captured and stored in the patient data file for future reference in HIMS. SVS integrate a digital image-capture system that allows the immediate capturing of still images from endoscopic procedures. A less-expensive alternative is a digital still image capture adapter, which can be connected to endoscopic camera systems. Digital still images usually can be recorded in jpeg, tiff, or bmp formats, depending on the necessary quality of the image to be edited (see Chapter 3).

## Data archiving

Customized OR software can be designed for individual needs. The following provides a general outline of the requirements of a data management system.

### Workstation

In the modern OR there should be an electronic workstation located in one corner. This workstation (Figure 9.4) has inputs via cables connected to the surface cameras, C-arm, ultrasound machine, and endovision camera. The cable input enters the OR panel where the composite AV signal is converted to S-video signal. The S-video output can be transmitted to any of the hanging display monitor (TFT screens) in front of the surgeon. Each screen has multiple cables; hence any image (fluoro/endovision/HIMS) can be viewed on any screen. The workstation also has a video processor with digital video (DV) output. HD video [6] is thus captured and recorded on a electronic storage device or on DVD for archiving and future editing. The OR panel is also connected via a two-way circuit to HIMS. The necessary information, including history, examination, X-ray, and computed tomography (CT) scan images, can be relayed to the hanging display monitor in front of the surgeon during the operation. At the same time, the OR details

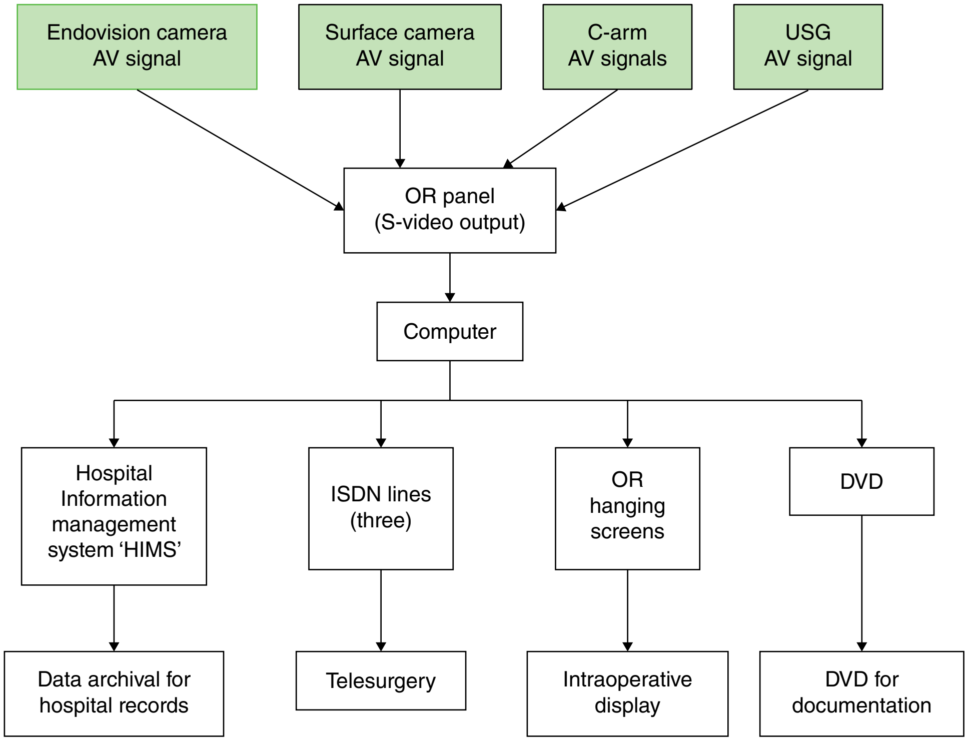

**Figure 9.4** Data management through the OR workstation. USG, ultrasound guided. Reproduced with permission of Mary Ann Liebert, Inc. Publishers.

can also be fed to HIMS for data archival. The workstation has three ISDN line connections.

#### Endovision camera

A signal can be taken directly from the lineout plug of the endocamera processing unit and inputted directly into an OR panel on the workstation.

#### Surface camera

At least three surface cameras should be present in the OR for video capture [7]. One camera is directed at the tabletop, and may be mounted on a light source or on a hanging boom. Another camera should be wall-mounted near the ceiling, and provides a view of the complete OR. This camera can be zoomed in or out as required by remote control. The third camera should be on one of the TFT screens. This position captures the face of the surgeon and is important during video conferencing when the surgeon is performing the procedure while watching the screen and simultaneously talking to the audience in the auditorium; these images will give the impression to the auditorium that the surgeon is facing and talking to them.

#### Fluoroscopic and ultrasound images

Most C-arm units [8] and ultrasound machines have a coaxial output jack on the back of the device. To arrange for data transfer, the coaxial jacks need to be connected with a coaxial cable and connected to the OR panel.

### Data relay

Various aspects need consideration for a state-of-the-art transmission relay system. Preliminary knowledge of the individual components of the relay system is essential for optimum utilization. These can be divided into components of local data relay and of the local and distant data relay system.

#### Local data relay components

The relay components are electrically interfaced to a control station within the OR. This control station has the capability to route voice, video, data, and physiologic information to and from the surgical suite. This capability is achieved through strategic equipment placement and an electrical infrastructure that allows the distribution of power and low-voltage wiring. Information is not only distributed within the OR but also to remote locations such as image archiving systems (PACS), classroom, and auditorium.

#### Modulator

The AV signal is converted into a UHF signal so that it can be received through a TV antenna input. Various electronic modulators are commercially available.

- A *combiner* has two inputs that respectively receive an NTSC combined visual and audio signal and a DTV signal wherein the NTSC signal and the DTV signal are in adjacent channels. The combiner has sharply tuned filtering interposed between the inputs and the output, tuned to pass the DTV signal while reflecting the NTSC signal such that these combine to form the combined output signal.
- An *RF amplifier* is used to convert a low-power radiofrequency (RF) signal into a larger signal of significant power.
- An *audio mixer* is an electronic device for combining, routing, and changing the level, tone, and/or dynamics of audio signals. The modified signals (voltages or digital samples) are summed to produce the combined output signals.
- A *video mixer* is an electronic device used to combine or “mix” two or more (PAL or NTSC) video signals, then output the sum as one new composite video signal. The picture-in-picture (PIP) and picture-on-picture (POP) support unit allows users to watch TV channels or DVD movies together with the computer screen, if a PC is connected to this unit. The PIP zoom function allows the PC image to occupy the main screen, with a video subwindow inserted. This video subwindow can take one of three sizes – one-quarter, one-ninth, or one-sixteenth of the screen – and can be relocated anywhere on the screen. POP is designed for cable TV channel preview. The channel preview can be set as 3 × 3 or 4 × 4 matrix with up to 16 channels at a time.

#### Optical fiber composite overhead ground wire

This type of cable (optical ground wire; OPGW) is used in the construction of electric power transmission and distribution lines. The optical fibers within the cable can be used for high-speed transmission of data. Because of the physical properties of image transference, optical fiber has a lower attenuation than coaxial cable and is not subject to electromagnetic interference.

#### Wireless local area network

Using electromagnetic waves, WiFi networks allow wireless devices to communicate with one another through access points or antennae. The advantages of a wireless network are the lack of having to install a wired network and the ability to communicate with mobile users.

#### Local OR data relay system

Most surgical meetings today devote a major session to the live operative workshop. Preliminary knowledge of the individual components of the relay system is essential for optimum utilization.

### Control room

A small control room in the vicinity of the OR is useful for the data relay system. The control room receives cable connections from all of the data-capturing components, and can route voice, video, and data to and from the surgical suite. Information is not only distributed within the OR but also to remote locations such as image archiving systems, classroom, and auditorium. One layout for electrical circuitry is shown in Figure 9.5.

To channel transmit OR proceedings to remote places, the composite AV signals from the OR is first relayed via cables to the control room. Here the signal is passed through the modulator, combiner, and video mixer (Figure 9.6). The emerging RF signal is thus transmitted to remote places, such as the plasma screen recessed in the wall of the OR. The operating surgeon through the microphone can interact with observers at remote places in a similar way. As described above, advanced video transmission features can be incorporated in the relay system via PIP and POP.

Similarly, signals can be relayed from remote places to the OR (Figure 9.6). For example, the AV signal from the auditorium is sent to the modulator in the auditorium and the emerging RF signals are then relayed to control room (Figure 9.7). The signal is then sent to the modulator, combiner, and audio mixer. The final amplified RF signal can be relocated to any remote place, including transmission to the plasma screen in the OR.

Four clinical scenarios for local data relay are shown in Figure 9.6. The first shows a teacher in a remote location accessing the live operative video display to monitor the progress of an operation. The AV signals from the OR are relayed to the video mixer and modulator. The signal from the modulator is mixed in the combiner and the emerging RF signal is transmitted to the teacher's room. The teacher can order specific commands about the procedure from this remote location to the operating resident in the OR through a wireless microphone. The audio signal is relayed to the audio mixer, and then to the speaker installed in the OR or through the modulator, which creates the RF signal that is relayed into the OR through the installed LCD screen.

The second scenario shows a teacher who is operating in the OR and relaying AV signals to the classroom or the auditorium for a two-way interactive operative workshop. Here, the AV signal is relayed to the video mixer for POP support or directed to the video modulator and combiner. The selected signal is amplified, switched into an RF signal, and transmitted to the plasma screens or projectors in the auditorium or classroom. The audio feedback from the audience is collected through the microphones and relayed to the audio mixer. After passing through the modulator and combiner, the RF signal is displayed on the LCD screen in the OR or, after passing through the audio switcher, an audio signal is relayed through the speaker installed in the OR.

The third scenario shows a teacher or observer who is remotely monitoring the progress in various ORs. The video signal from the various ORs is transmitted to the

modulator and combiner, and as an RF signal is then sent to the teacher. The teacher can select the individual OR they wish to monitor using a channel selector.

The last scenario shows a surgeon who wishes to watch the OR proceedings on DVD. The video signal from the OR is fed into the video mixer. The DVD recorder then records the output signal, and a DVD can then be given to the surgeon to watch.

For teleconferencing to distant places and countries, an ISDN network facility needs to be connected to the computer in the workstation in the OR. Just like a regular telephone line, the ISDN enables the OR transmission to be dialed to any ISDN location anywhere in the world. Through the B channel, the ISDN line can support simultaneous two-way communication for two devices, such as a computer and a telephone, or a computer and a video camera for teleconferencing. Through the ISDN line, data can be sent to remote locations and at the same be received by the workstation, sent to the control room, and then transmitted anywhere else required.

## Conclusions

A dedicated OR design is essential for endourology and allows efficient state-of-the-art care in the modern information technology era. The older cart-based paradigm restricts the ergonomic configuration of the OR and creates potential mechanical, electrical, and biologic hazards to the patient and OR staff. In order to decrease clutter, ease personnel movement, improve ergonomics, maintain the sterile field, and facilitate the use of advanced imaging, an appropriately designed OR is essential. These design elements may prove to be critical to the next generation of dedicated fluoroscopy-compatible endourology suites, and will facilitate further advances in procedures.

The data archival, management, and relay system enables efficient and cost-effective transmission of data. This arrangement has been used extensively in our own hospital with resultant high-quality video recordings being presented at a number of national and international surgical meetings. In addition to being used for recording video, members of the OR staff can refer to the video display to monitor the progress of the operation, and it can be used as a teaching aid for residents present in the OR during the procedure.

## Introduction/background

Urologists developed endoscopy in surgery with a focus on lower tract endoscopy in the late nineteeth and early twentieth centuries, with pioneers such as Grunfeld, Nitze, Ringleb, Goldschmidt, Desormeaux, Kelly, Brenner, and Casper. Luminaries such as Beer, Luys, Young, Davis, Buerger, Albarran, Heitz-Boyer, Goldschmidt, Stern, McArthy, Nesbit, Alcock, and Flocks continued to evolve the techniques and equipment. Retrograde and antegrade endourologic approaches to the upper tract were introduced by Cromwell and Kelly and subsequently developed by Marshall, Rupel and Brown, Fernstrom and Johansson, Goodwin, Bagley, Clayman, Smith, Lange, Segura, and Amplatz [1, 2].

The term "endourology" was coined by Drs. Elwin Fraley, Arthur Smith, Paul Lange, and Ralph Clayman and their team at the University of Minnesota. The principles and techniques associated with endourology has become a cornerstone for what we teach trainees in order to practice modern-day urology [3]. Medical educators for endourology continually search for the optimum modalities and methods for both skills training and competency assessment.

Taxonomies for the acquisition of technical skills outside of surgery have been developed by Dreyfus and Dreyfus, Dave, and several others [4, 5]. Figure 10.1 shows a combination of these two taxonomies and provides a matrix for classifying and understanding the progression of technical skill for urology [6].

As a trainee moves from what Dave's taxonomy describes as imitation to manipulation, what is happening according to Dreyfus and Dreyfus is a maturation of recollection of knowledge from non-situational to situational. This probably represents the "low bar" for the end of a training program prior to practice as it stands today. As someone evolves from manipulation to precision, their recognition of cues and knowledge moves from decomposed to a more holistic view. This translates to moving from "competent" to "proficient" and represents what happens early in one's independent practice. Note that there are still errors being performed as one's brain wants to begin multitasking and shifting to "automaticity" mode that represents less cognitive load. The evolution from precision to articulation is when we can start to multitask and represents a parallel transformation to "expertise." Here, our decision-making abilities become less analytical and more intuitive, freeing up the cognitive load to be able to multitask. This is probably where most practicing endourologists are functioning for most skills that are performed on a regular basis. Becoming a true "master" represents high-functioning on autopilot. At this level, an individual's awareness has evolved from monitoring the situation to completely being absorbed (virtuoso). Invention and skillful troubleshooting happen naturally during this phase.

The Halstedian apprenticeship model heavily relies upon the accumulation of considerable operative experience gathered during several years of demanding training [7]. Such "on the job training," with the combination of attestations, case volumes, skills evaluations, and index cases, has been accepted as effective, although correlation to "objective" performance educational outcomes has been poorly studied for endourology.

In parallel, the evolution of endourology has been accelerated and represents a core skillset for the practicing urologist. There are unique learning objectives for endourology related to image-guided surgery, rigid and flexible scope manipulation, advanced Seldinger techniques, endoluminal manipulations, laparoscopy, and robotics. The learning curves associated with these skillsets represent [3] possible barriers to optimal practice and endourology fellowships are often required to obtain proficiency and expertise in these skills. The increasing awareness of patient safety, along with the growing

debate on the ethicality of completing initial learning curves on patients, and the necessity of assessing the competency in a more reasonable fashion, also urge the clinical providers to seek an adjunct modality to enhance the traditional education and training pattern.

Surgical performance in endourology is based on a combination of both technical and nontechnical skills. Medical simulation provides a no-risk platform for learners not only to acquaint and develop new skills, but also to refine and perfect their abilities to achieve expertise and mastery [3]. When integrated into medical education, simulation not only enables the trainees to bypass the early error-prone period and reduce the steepness of the technical skills learning curve [7], but also develop nontechnical skills during training, which all contribute to secure the patient's safety and well-being [8].

## Current state of simulation in endoscopic urological training

> *Engineering is the art of modeling materials we do not wholly understand, into shapes we cannot precisely analyze so as to withstand forces we cannot properly assess, in such a way that the public has no reason to suspect the extent of our ignorance.*
>
> (Dr. AR Dykes)

Simulation development for training in endourology, as was the case for all of healthcare, was more of an art than a science. The fledgling healthcare simulation industry, in an effort to protect intellectual property, would often keep their early prototypes a close secret and would subsequently waste precious time and money in re-engineering major design flaws with advanced prototypes or, worse yet, compromise on learning objectives. The excitement associated with the promise of simulators as a solution for both training and assessment turned into disillusionment for many healthcare educators.

Today, a boom of information technology, wireless technologies, material science, manufacturing, and, most important, the conceptual evolution of simulation-based education are influencing simulation in endourology. Simulation, as a valid and safe supplement modality in healthcare education, is slowly becoming embraced by academic medical centers around the world, and is being used to train and assess all of the domains that are linked to performance in healthcare including technical and nontechnical skills for both individuals and healthcare teams.

Tables 10.1–10.6 summarize the available simulators for urological skills training. They are classified by procedural application and simulator type.

## Validity evidence

The validity evidence of these simulators are posted in these tables (Tables 10.1–10.6). Validation studies are indispensable to ascertain the appropriateness of simulation-embedded curriculum for a given purpose; for instance, whether a curriculum actually transfers knowledge and whether that transfer actually translates into improved performance.

When interpreting the data in these tables, one must keep in mind that much of the literature to date in endourology has presented validity evidence, according to Gallagher et al. [9] and McDougall et al. [12], which is based on the 1974 American Psychological Association (APA) Standards for Educational and Psychological Tests [10]. The 2014 [11] version of the APA Standards represented a significant shift in philosophy. Current literature validity evidence in healthcare is slowly shifting with our APA colleagues towards this modern approach to validity [2, 11] and is now being presented with a more holistic approach, whereby construct validity represents the whole of validity and is defined around a purpose. For the purposes of interpreting the past literature and integrating it into the current approach to interpreting validity evidence, we can think of construct validity as being made up of several aspects that don't "stand alone," but contribute evidence towards that central "construct," Classically, face validity "aspects" is completely subjective and does it seem to accomplish what it is trying to at "face value." Some aspects of realism of the simulator are captured here, but are not to be confused with "acceptability." Content "aspects" of validity addresses whether the detailed content of the curriculum/trainer address the learning objectives. It, too contributes evidence around the "construct" towards a judgment of the appropriateness of the simulator as a teaching tool. Concurrent validity "aspects" contribute to the "construct" through examining the extent to which the results of the test correlate with the gold standard known to measure the same domain. Predictive validity aspects examine the extent to which an assessment predicts future performance. Discriminant validity "aspects" examine the ability of a simulator to differentiate ability levels within a group with similar experience; it tests whether measurements that are supposed to be unrelated are unrelated [12]. Much of the literature to date examines discriminant aspects of validity evidence and misclassifies this as distinct "construct" validity in the modern-day interpretation.

## Emerging technologies and future directions

Fidelity, or the degree of similarity compared to reality, is an important factor to consider during the development of simulation devices. The degree of fidelity should align with the learning objectives and desired outcomes. Depending upon the application and purpose, anatomic, physiologic, emotive, and tissue fidelity may all be important and distinct elements [2].

Emerging technologies such as virtual reality (VR), augmented reality (AR), mixed reality (MR), three-dimensional (3D) printing, and conformable sensors all offer possible opportunities to bridge the gaps between the curricular needs and simulator development. By utilizing and combining these modalities, simulation systems are being created with more lifelike, precise, and patient-specific features, could closely mimic the interactive clinical environment in real time. An effort towards an open-source standardized platform that connects systems from different manufacturers and modalities is being created through a US Department of Defense contract that promises to accelerate the capabilities for simulation across healthcare, but especially in surgery. This is known as the Advanced Modular Manikin program (https://www.advancedmodularmanikin.com/). It is a combination of these technologies and projects that will lead to true patient-specific rehearsal opportunities.

The benefits and application of simulation are not limited to the proficiency-based disciplines; they are also valid in the vast majority of disciplines and domains of healthcare. Given the massive investment, ongoing consumption, and the time needed for validation, simulation-based curricula have had difficulty in *directly* demonstrating a return and benefit of investment in the short term. Hence, further studies investigating the effectiveness of simulation in improving patient safety and outcomes should be encouraged. In summary, the training and assessment of endourologic skills is and will continue to be improved with the use of ever-evolving simulation technologies; moving our discipline towards a "competency" model of education and privileging.

Video 10.1 outlines endoscopic training and simulation.

**Table 10.1** Available simulators for urethrocystoscopic skills simulation training.

| Type | Trainer/ simulator | Manufacturer | Built-in assessment | Cognitive component | Haptic feedback | Face validity | Content validity | Construct validity | Concurrent validity | Predictive validity | Discriminant validity | Cost (USD) | Ref. |

# Part 2 Patient Positioning for Percutaneous Access

## 11

## Patient Positioning, the Supine Position, and the Rationale of ECIRS

*Cesare M. Scoffone & Cecilia M. Cracco*

*Department of Urology, Cottolengo Hospital, Torino, Italy*

### Introduction

Prone patient positioning for percutaneous nephrolithotomy (PCNL) as a practice has been inherited from radiologists who employed it for the technique of percutaneous nephrostomy for the drainage of hydronephrotic kidneys. In fact, they used to put the patient in a prone position because in this position they could directly puncture the renal pelvis without passing through the renal parenchyma [1]. At a later time the pioneering urologists who developed the PCNL technique took the renal puncture out of the radiologists' hands [2]. This change required some time to be adopted, and in many centers the habit of using renal access by radiologists was maintained until recently [3–6]. Urologists started establishing for themselves more effective and safer methods of percutaneous access to the kidney via the calyceal system [2, 7], but changing the patient's position was not considered a relevant issue.

Over the years percutaneous access to the collecting system was occasionally achieved via supine or oblique positions when required by particular clinical conditions or challenging cases, but the prone position remained the norm. Therefore prone PCNL became the traditional approach following its introduction in the 1970s, and has remained so until nowadays [8]. It is only recently that urologists have started to increase their familiarity with the supine approach to PCNL, and this method is now used in about 20% of centers worldwide but with a very limited practice in North America and Australia [6, 9–13].

### The supine and supine-modified positions for PCNL

Dr. Josè Gabriel Valdivia Urìa from Zaragoza (Spain) started performing percutaneous renal surgery in the supine position with an air bag under the flank in the late 1980s. He first reported his positive experience with supine PCNL in a national journal in 1987 [14], and few years later [15, 16] in international journals, but his proposal did not become popular among urologists at that time.

It was only later that other urologists from all over the world started to adopt and appreciate the pure supine position, especially for high-risk and obese patients [17–21]. Additionally a variety of supine-modified positions for PCNL, including the modified supine [22], Galdakao-modified supine Valdivia [23, 24], semisupine [25], and supine-oblique [26] positions were described.

### The anesthesiologic advantages of the supine positions

Anesthetists started highlighting their problems with the prone PCNL position and sharing them with urologists only in the last few years [27–31], in spite of their extensive previous experience with this position for much longer neurosurgical or orthopedic procedures [32–43].

The variety of original devices proposed over the years (like the Montreal mattress, various paddings, the Pronew protective helmet, the ETView tracheoscopic ventilation tube, and reinforced endotracheal tubes) prove the anesthetists' concerns about some of the major hazards of the prone position [44], including accidental extubation and kinking of the endotracheal tube during positioning of the patient, hampered ventilation and altered circulation, torsion of the neck, pressure and transient ischemia of the eyeballs, overstretching, and pressure injuries of the peripheral plexuses [45]. Subsequently urologists became more sensitive to this kind of problem too [12, 46–51].

In the supine and supine-modified positions the anesthetist enjoys optimal cardiovascular and airway control,

has an easy access to the neck if central venous cannulation or any other invasive monitoring such as intraarterial catheters becomes necessary (although seldom required), easily maintains proper monitoring throughout, may effortlessly perform resuscitation maneuvers in case of emergency, and does not deal with all the cardiovascular, ventilatory, hemodynamic, pharmacokinetic, or metabolic effects typical of the prone position [48, 52, 53].

## The urological and management advantages of the supine positions

1) Positioning the patient in the supine position is easy and comfortable, with no intraoperative changes as there are for prone PCNL, instead requiring to turn the patient twice (at the beginning of the procedure from supine to prone, before starting standard PCNL and after having applied the ureteral catheter for retrograde pyelography, and then at the end from prone to supine, before awakening the anesthetized patient). Therefore there is less of a need for nurses, less occupational risk for all the involved operators due to the shifting of heavy loads, less risk of pressure damage to the peripheral nerves of the patient, and the possibility of preparing a single definitive sterile draping of the patient [12, 24, 54].
2) The antegrade surgeon can work sitting down, with the hands outside of the fluoroscopic field, as the X-rays are roughly perpendicular to the axis of the needle and of the percutaneous tract afterwards [12, 24, 54]. Overall X-ray exposure during the percutaneous procedure may also be reduced, thanks to the combined retrograde ureteroscopic contribution to PCNL (see later).
3) The risk of colon injury seems reduced, because in the supine positions the colon moves away from the puncture area by an average of 2.5 cm, decreasing the risk of its perforation compared to prone positioning [55–59].
4) The horizontal or slightly downward inclination of the Amplatz sheath maximizes irrigation outflow, consequently lowering intrarenal pressures. Low intrarenal pressures imply less risk of pyelovenous, pyelolymphatic, and pyelointerstitial backflow of bacteria and endotoxins, and thus less uroseptic risk [60], less fluid resorption, thus less risk of fluid imbalance [48], and better spontaneous drainage of stone fragments [12, 24, 54].
5) The supine positions are optimal and unique for the treatment of upper tract urolithiasis in urinary diversions (conduits and orthotopic reservoirs), as well as very useful in cases of combined opening of ureteral strictures or ureteroileal stenoses [24, 54].

## Disadvantages of the supine positions

1) In the supine positions the kidney is more mobile than in the prone position, especially in very slim and obese/morbidly obese patients, because it is not kept fixed by gravity combined with the rigidity of the posterior abdominal wall, and by the scarce or soft perirenal/pararenal fat tissue of such patients. Because of this hypermobility and respiratory movements the renal puncture may become more difficult. Solutions: a coordinated abdominal counterpressure on the mobile kidney may be exerted by the surgeon with the hand free from the puncturing needle or other devices. If the patient is under general anesthesia a brief apnea in maximal inspiration may help. The introduction through the access needle of the "through and through" guidewire (obtaining the so-called kebab or skewered patient) may additionally contribute to the reduction of the kidney hypermobility, at least during tract dilation and Amplatz sheath application [54].
2) The optimal irrigation outflow decreases the filling of the collecting system; thus nephroscopy might be difficult because of the limited distension of the renal cavities, sometimes further worsened by the active aspiration of the ultrasonic lithotripter. Solutions: filling of the collecting system may be transiently and delicately increased by the additional irrigation from a syringe or by a manual pump from the retrograde ureteroscope; temporary elevation of the saline bags may also help to improve endoscopic vision and working space if needed.
3) A superior calyceal puncture may be more challenging. Solutions: the anesthetist may help with apnea in maximal inspiration, if the patient is under general anesthesia. A renal displacement technique has also been described [61], although it might be at risk of parenchymal kidney damage. In any case, in supine positions superior calyces are usually entered in a retrograde manner by ureteroscopy rather than through the usual lower pole puncture, avoiding the risk of upper pole access implying a high risk of pleuric and hepatosplenic injury. In fact, in this position the angle between the upper and lower calyces is wider [12, 54].
4) The tract length might be longer, especially in obese patients, with decreased nephroscope mobility, and more torque on renal parenchyma, meaning a greater risk of bleeding [62]. Solution: use extra-long equipment in the case of obese patients.
5) The working space is very restricted, if compared to the large working field of the prone position. Manipulation of some rigid nephroscopes may also

be awkward [24, 54]. Solutions: elevation with jelly pillows opens the angle of the flank to be operated. Putting the patient very near to the border of the operating table prevents the collision of the nephroscope (especially those with the light cable directed downwards) with the edge of the operating table. Nowadays most rigid nephroscopes have all the cables and irrigation/working channels on their upper part, so collision is not a relevant problem anymore.

## The Galdakao-modified supine Valdivia position

In the 1990s Dr. Gaspar Ibarluzea from Bilbao (Spain), facing a difficult post-extracorporeal shock-wave lithotripsy (ESWL) Steinstrasse, tried the combination of the supine Valdivia position with a modified lithotomic arrangement of the lower limbs. After having appreciated the urological, anesthesiologic, and practical advantages of this new position he started using it regularly for left PCNL (because of the fixed features of the radiological table he used) and named it the Galdakao-modified supine Valdivia (GMSV) position [23, 63].

The GMSV position, combining the supine Valdivia position with a modified arrangement of the lower limbs, presents all the anesthesiologic, urologic, and management advantages of the supine positions, additionally supporting an easy simultaneous combined antegrade and retrograde approach to the upper urinary tract for stone treatment with both rigid and flexible endoscopes, i.e. endoscopic combined intrarenal surgery (ECIRS) [23, 24, 54].

## Patient positioning in the GMSV position

- The operating table should be radiolucent, mobile in order to leave the abdomen free of radiopaque interposed bars, able to easily host a C-arm for fluoroscopy, and arranged with padded leg stirrups for the modified lithotomic position of the lower limbs. The floor underneath is covered by absorbent paddings in order to prevent fluid spilling.
- The operating room, being very crowded, requires thorough, standardized, and coordinated preparation, achieved through well-organized team work which includes the urologists, the aneasthetist, and all the nurses. Ultrasound and fluoroscopy are placed on the side to be operated (Figure 11.1a), the anesthetist and the required equipment are behind the head of the patient (Figure 11.1b), and lithotripsy devices (laser and ballistic/ultrasonic lithotripters) are behind the antegrade surgeon, sitting in front of the flank to be operated (Figure 11.1d). The C-arm with the radiology technician (Figure 11.1c) and the video tower (Figure 11.1d) should be in front of the antegrade surgeon and on the other side of the patient. The antegrade irrigation should be near the C-arm and the head of the patient (Figure 11.1c), retrograde irrigation near the video tower and the legs of the patient (Figure 11.1d), the scrub nurse between the antegrade and the retrograde surgeons, with the retrograde surgeon between the lower limbs of the patient (Figure 11.1d), and the antegrade table is behind the antegrade surgeon. The retrograde scrub nurse table is placed between the antegrade and the retrograde surgeon. The organization differs in the case of right and left surgery [64]. The operation modes of all the devices must have been previously checked; all required materials like lead aprons, jelly pillows, and paddings must be ready in the operating room. All the operators must work without obstacles, having everything they need within arm's reach and positioned comfortably.
- The patient lies supine, with the flank to be operated very near to the border of the operating table to allow free mobility of the nephroscope once the patient has been definitely arranged (Figure 11.1a).
- The flank to operate on is elevated 20–30° with plumcake-shaped jelly pillows (Figure 11.1a) (or towels, a 5 l saline bag, or an inflatable cushion). This inclination may be adapted to the patients' requirements: in very thin patients, or in those with mild forms of retrorenal colon, or in case an upper calyceal access is needed, the elevation of the flank should be increased >30°, sometimes obtaining an almost perpendicular position, with the patient largely lying on the opposite flank.
- The first reference line, i.e. the posterior axillary line, is marked. This is the anterior limit of the puncture (Figure 11.1a).
- The leg of the side to be operated is arranged, extended, and only slightly abducted; the contralateral one is lifted, flexed, and well abducted, with both lying on padded stirrups and fixed (Figures 11.1a–c). Children may avoid the classical lithotomic position with padded stirrups for the lower limbs, and a simple stable opening of the legs on the operating table may be sufficient.
- The arm on the side to be operated is bent at the thorax on an adequate support (we use soft towels or a cushion), and the contralateral one lies abducted less than 90° on a padded support for anesthesiological management (Figures 11.1a,b).
- Then the other two reference lines, i.e. the twelfth rib cranially and the iliac crest caudally, are marked (Figure 11.1a), representing the posterior natural limit,

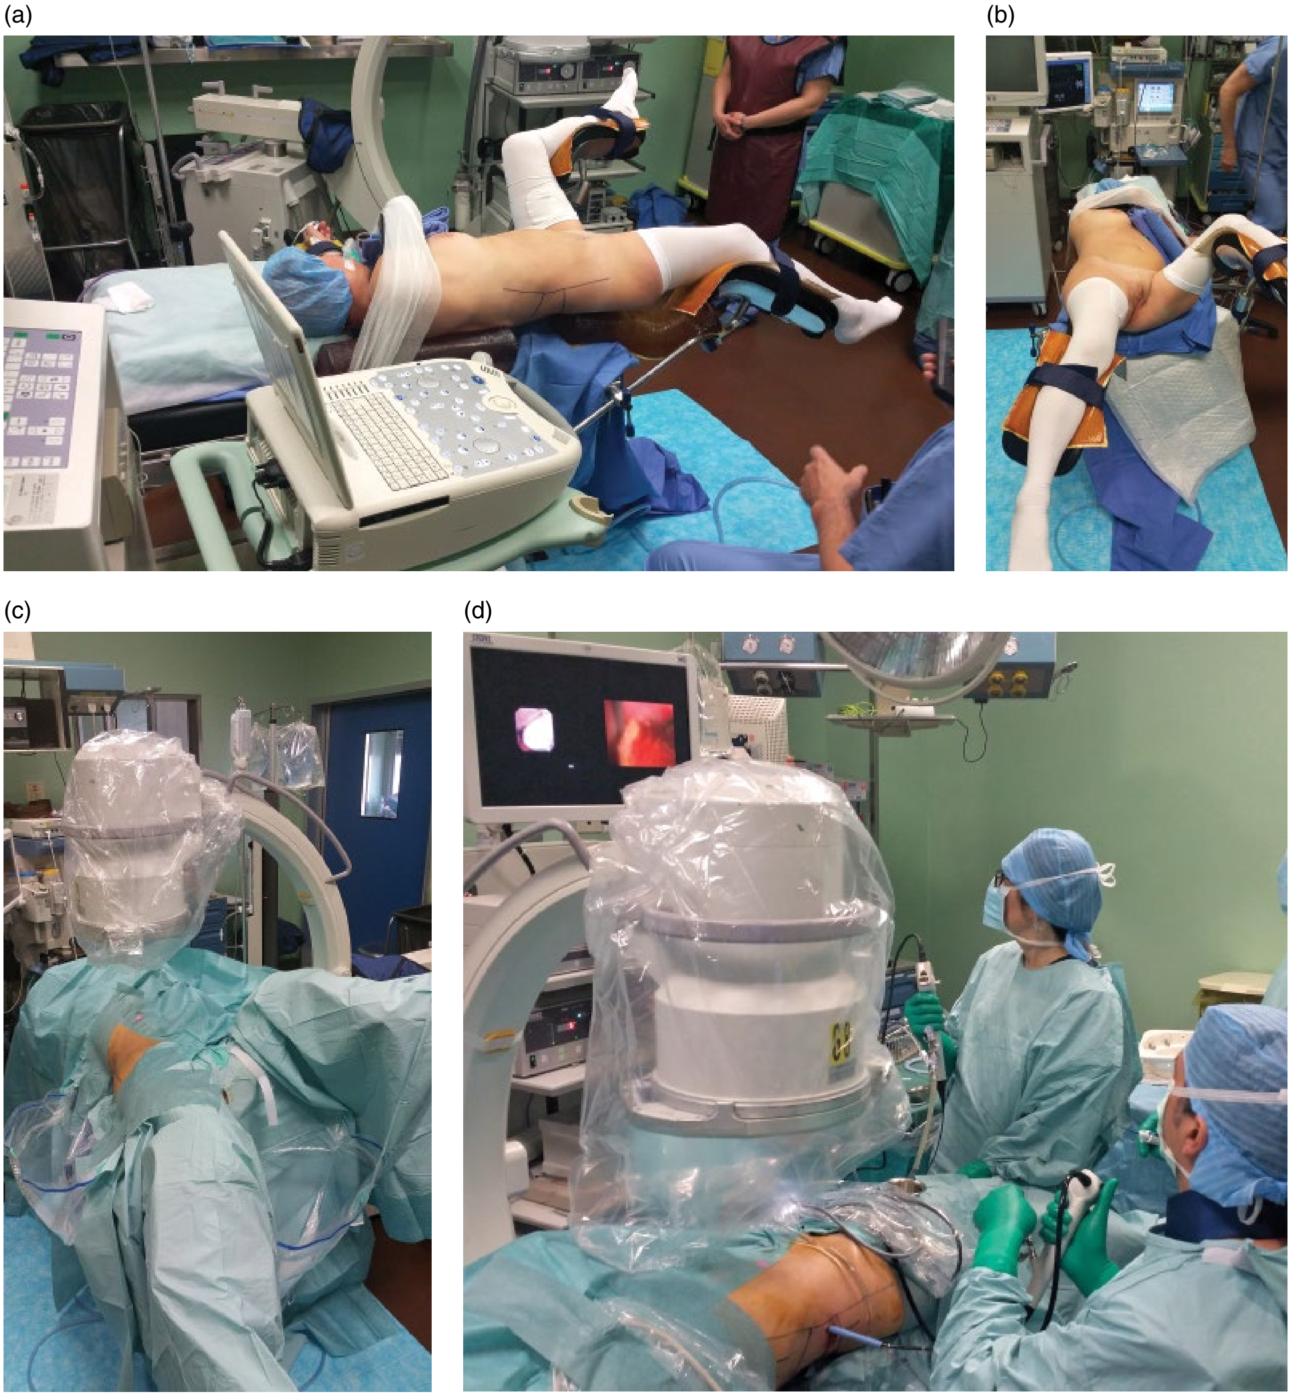

**Figure 11.1** Patient in the Galdakao-modified supine Valdivia (GMSV) position: (a) view of the elevated flank with the reference lines and (b) of the modified lithotomic position of the lower limbs. (c) After thorough positioning sterile drapings are applied, with irrigation bags to avoid fluid spillage; (d) the flank and the perineum are left free for antegrade and retrograde access respectively.

the lateral margin of the paravertebral muscles representing the posterior natural limit.

- In obese patients the fat falls on the side opposite to the one to be treated and might be fixed and flattened by applying strips of sticking plaster.
- Particular care should be taken when positioning a patient with skeletal deformities, adapting it in different ways from time to time, and paying particular attention to avoid pressure damage during the procedure.

- The unique sterile draping is an assembly of adhesive drapings including those from the cystoscopy set, all fixed with adhesive strips, provided with two bags, one under the flank and the other under the perineum, to avoid fluid spilling (Figure 11.1c) [64].

## Additional advantages of the GMSV position

A combined retrograde approach is comfortably performed and combined with antegrade surgery, thanks to the easy access to the urethra. Of course, retrograde access is also possible in prone-modified positions [65–67], although is evidently less comfortable and ergonomic.

The possibility to gain a suitable retrograde working access during PCNL enables endoscopically guided percutaneous access for a safe renal puncture, integrated with fluoroscopy and ultrasound, the standard imaging modalities, and provides an effective tool able to improve stone clearance, decrease the number of percutaneous accesses, and reduce overall radiation exposure. This is ECIRS, i.e. endoscopic combined intrarenal surgery [12, 24, 54].

## ECIRS, the rationale

The conceptual value of ECIRS extends beyond a safe endoscopically guided renal puncture, or the possibility to improve stone clearance through a single percutaneous tract thanks to the simultaneous contribution of the flexible retrograde ureteroscopy. ECIRS is a comprehensive approach to PCNL, allowing for versatile personalized stone management, and a perfect tailoring of all the intraoperative choices to the real-time situation of the patient and on the dynamic anatomy of the collecting system containing the urolithiasis on the whole [54].

In ECIRS retrograde flexible ureteroscopy replaces the step of the cystoscopic ureteral catheter application for retrograde pyelography, allowing preliminary direct visualization of the urethra, ureteral orifice, ureter, ureteropelvic junction, pelvis, and calyces with their infundibula, and the instructive evaluation of their dynamic features for an optimal planning of the following strategy. Of course, if the upper tract is not compliant, the retrograde approach must not be forced, and the traditional ureteral catheter is applied, but when possible it is advantageous and safe, as with applying a urethral catheter using vision instead of inserting it blindly. The diagnostic role of retrograde flexible ureteroscopy goes on intraoperatively, assisting all the steps of the percutaneous renal access, stone treatment, and exit strategy.

The active role of retrograde flexible ureteroscopy is optional (ECIRS may be used when there is no other retrograde contribution other than a diagnostic one), however it may be essential for safe antegrade or retrograde guidewire application to facilitate renal access and to improve stone clearance, managing or treating stones which are difficult to reach through a single percutaneous tract.

Of course, the idea of using flexible ureteroscopy as an adjunct to PCNL is not new at all [7, 68–72], but for various reasons (probably economic, because a second surgeon is required, and the use of flexible ureteroscopes with all their devices and the risk of rupture may constitute an additional relevant cost) [73] was never fully accepted and considered an essential step of PCNL, but rather an occasional and complementary contribution in difficult cases. Nowadays flexible ureteroscopes are ubiquitous in clinical practice, more advanced, miniaturized, and durable, with the additional option of single-use digital flexible ureteroscopes. So only the experience of the operators and their openness to try innovative solutions are needed for its widespread use during PCNL.

## The diagnostic role of retrograde flexible ureteroscopy during PCNL

1) The lower urinary tract is preliminarily evaluated. Simultaneous problems like false urethral passages, large obstructing and easily bleeding prostatic adenomas, calcified intravesical stents, or tight ureteral orifices may be identified and dealt with.
2) The dynamic anatomy of the ureter and upper urinary tract is preliminarily appreciated. Ureteral spasms or strictures, ureteral stones, a tight ureteropelvic junction, inelastic infundibula, and staghorn stones strongly adhering to the mucosa of the calyx may be recognized in advance, adapting the surgical strategy and the kind and size of the instruments to the patient, without forcing the anatomy and causing damage.
3) Preliminary evaluation of the stone features (not only those already known from preoperative computed tomography scanning such as their number, hardness, location, shape and size, but also dynamic characteristics like mobility and possibility of displacing them) is carried out. This may also help in the planning of the PCNL strategy.
4) Each step of the renal access (puncture, guidewire application, dilation of the access tract, Amplatz sheath application) (Figures 11.2–11.6) may be checked endoscopically (Figures 11.2d, 11.3c, 11.4b, 11.5b, 11.6b), integrating ultrasound (Figure 11.2a)

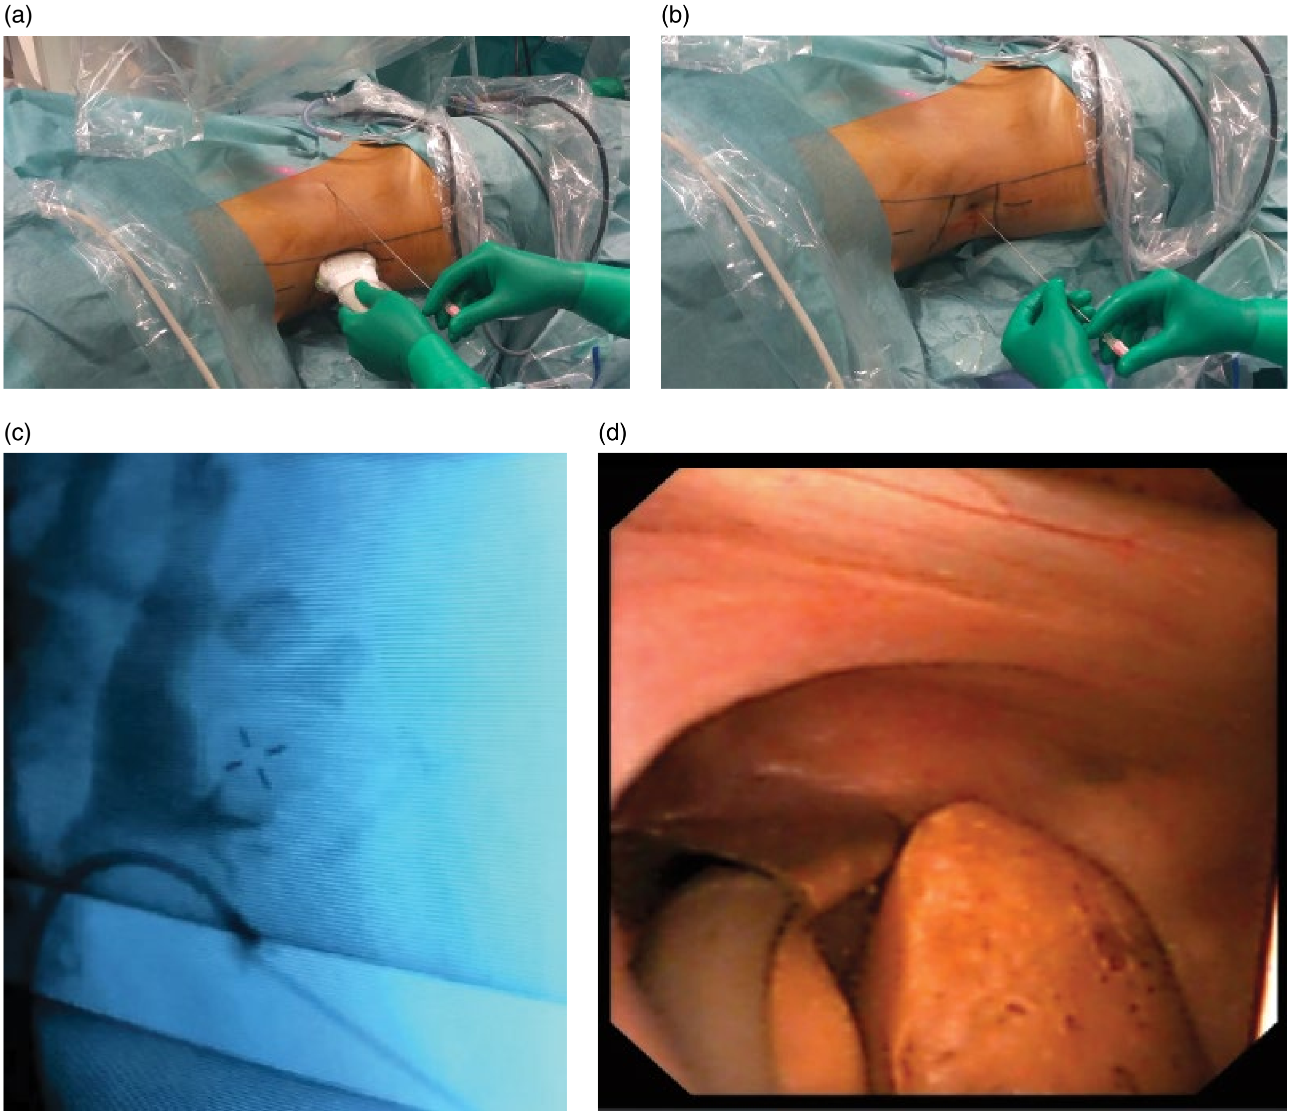

**Figure 11.2** (a) Ultrasound-checked (b) fluoroscopy-guided renal puncture may be followed endoscopically with retrograde flexible ureteroscopy (c, fluoroscopy; d, digital view).

and fluoroscopy (Figures 11.2b,c, 11.3a,b, 11.4a, 11.5a, 11.6a). In this way overall radiation exposure may be significantly reduced, thanks to the direct endoscopic control [74].

5) Antegrade lithotripsy through the rigid (Figure 11.7a) and the flexible nephroscope (Figure 11.1d) can be followed retrogradely, in order to avoid descent of fragments below the ureteropelvic junction.
6) Final endoscopic exploration of all calyces in search of residual fragments, in combination with the flexible nephroscope (Figure 11.8a), may be performed, aiming at an optimal stone-free rate.
7) A final evaluation of all renal cavities supports the decision for a stentless or a stented procedure, along with the assessment of the descent of the contrast medium from the pyelocalyceal system below the ureteropelvic junction and within the ureter.

## The active role of retrograde flexible ureteroscopy during PCNL

1) Guidewire application from the percutaneous renal access down the ureter may be endoscopically assisted (Figures 11.3a,b), but if the wire initially coils within the pelvis or a renal calyx, antegrade retrieval of a retrogradely inserted guidewire is also possible, after the

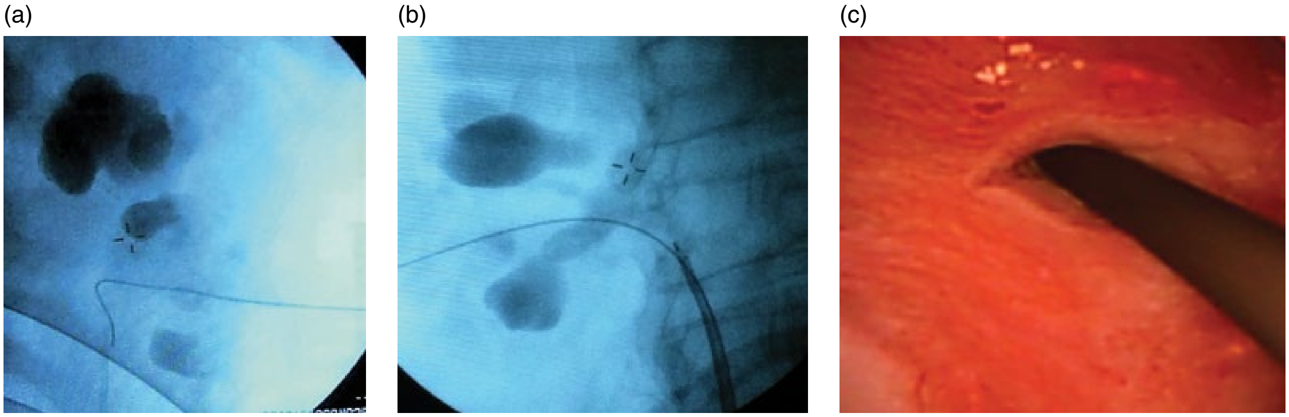

**Figure 11.3** The hydrophilic guidewire may be applied antegradely and descend into the ureter (a, fluoroscopy), sometimes guided by the flexible ureteroscope (b, fluoroscopy), also checking the guidewire exiting from the renal papilla (c).

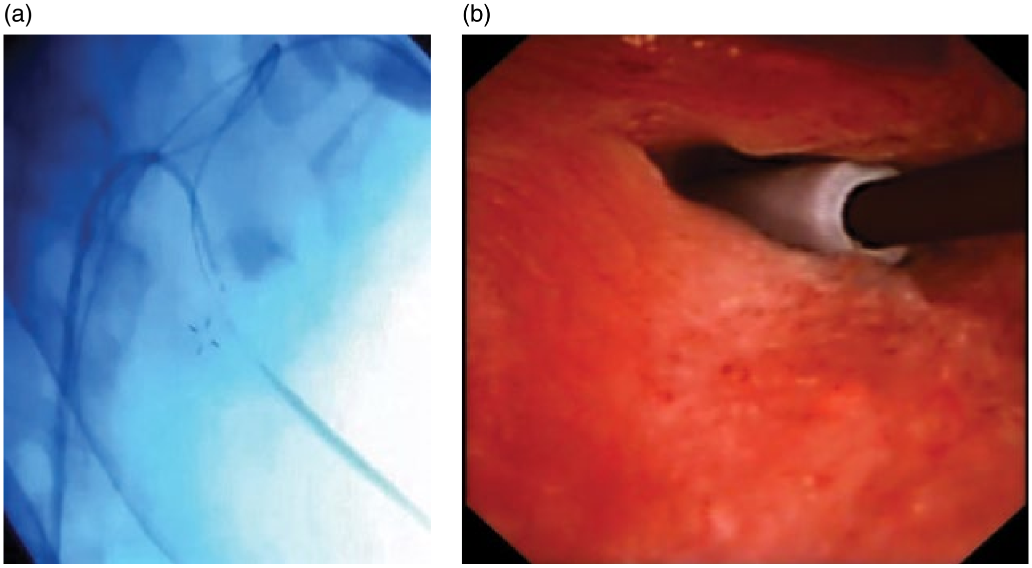

**Figure 11.4** Insertion of a fascial dilator: (a) fluoroscopic and (b) endoscopic control.

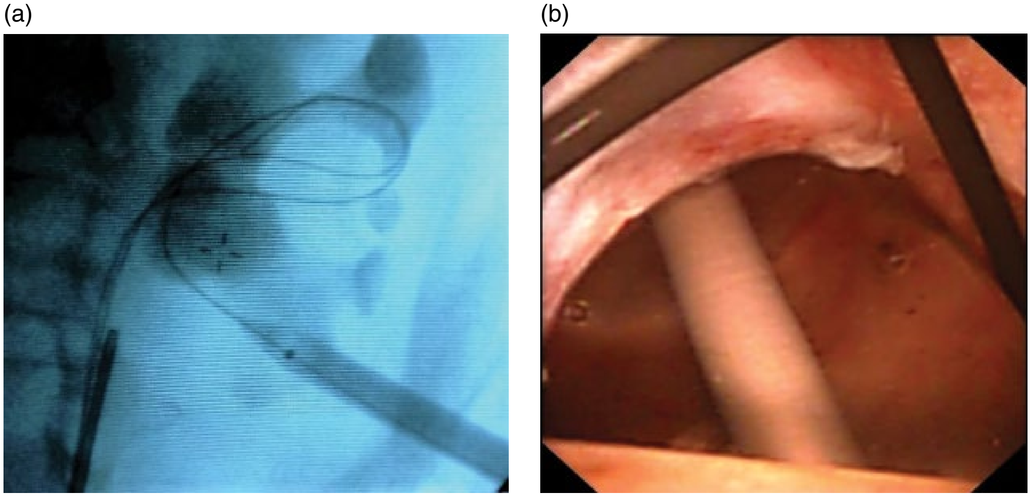

**Figure 11.5** Insertion of a balloon dilator: (a) fluoroscopic and (b) endoscopic control.

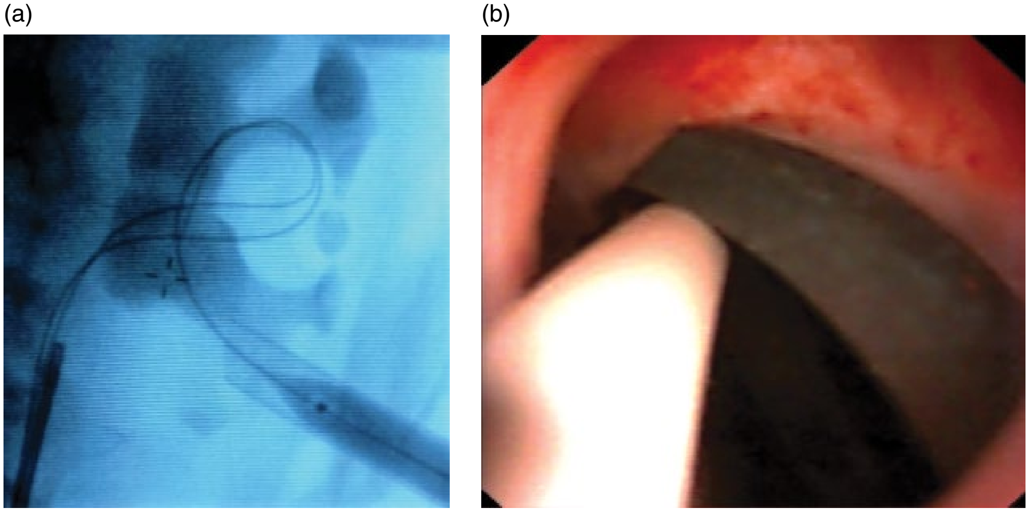

Figure 11.6 Insertion of the Amplatz sheath: (a) fluoroscopic and (b) endoscopic control.

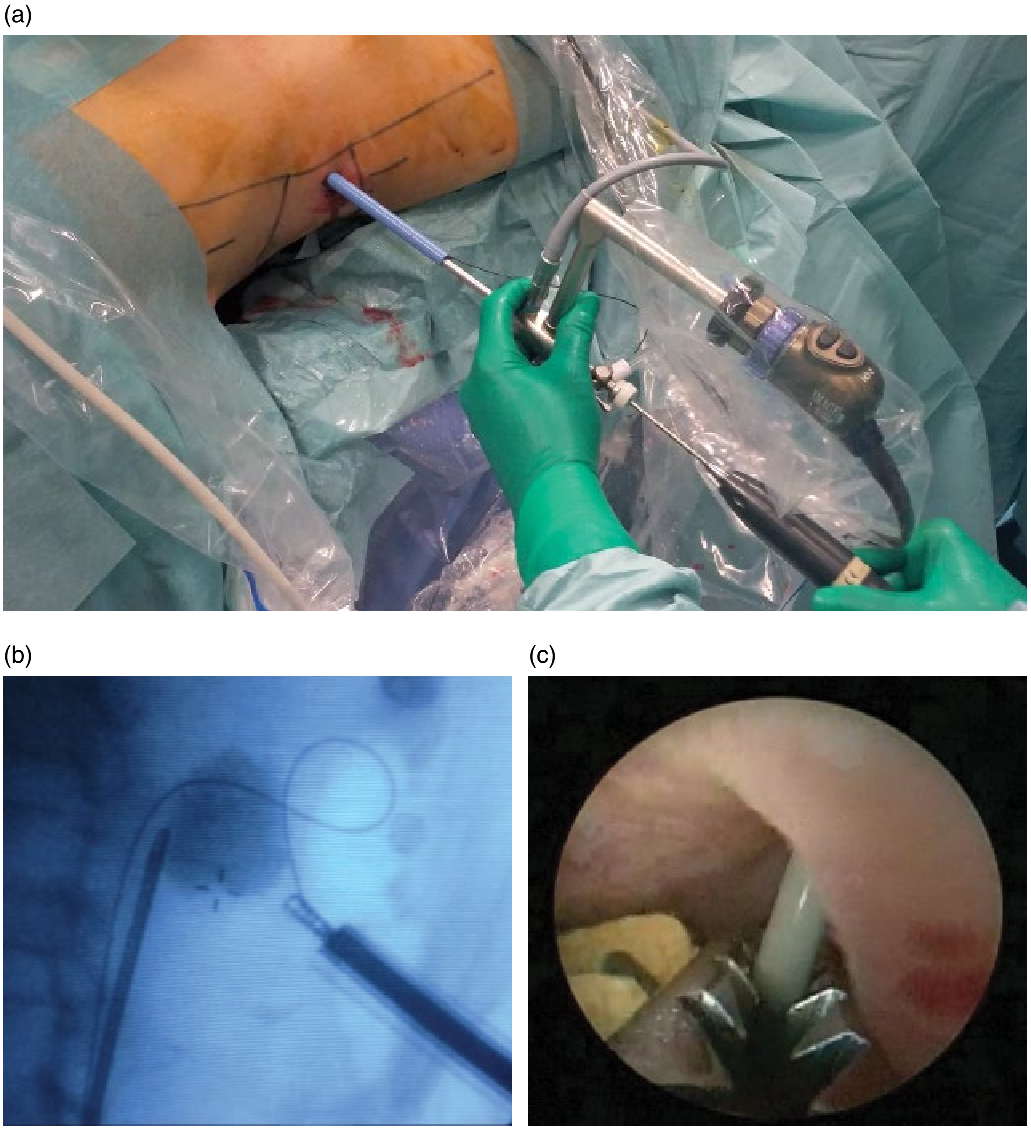

Figure 11.7 Rigid nephroscope and ballistic/ultrasonic lithotripsy (a), after extraction of a retrograde guidewire from the Amplatz sheath (b, fluoroscopy; c, endoscopy).

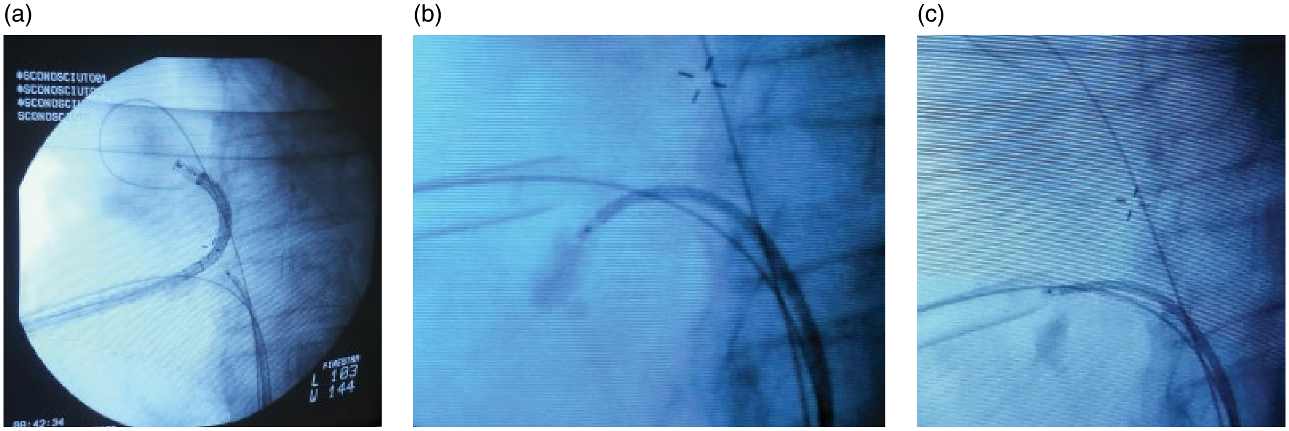

**Figure 11.8** Cooperation between flexible nephroscope and flexible ureteroscope, exploring all the calyces in search of residual fragments (a, fluoroscopy). Sometimes stones are located in calyces parallel to the Amplatz sheath (b, fluoroscopy), so the contribution of the retrograde flexible ureteroscope becomes essential and fragments may be snared within a basket and delivered outside through the Amplatz sheath (c, fluoroscopy).

percutaneous access has been gained (Figures 11.7b,c), obtaining the maximally safe "kebab" patient.

2) All the steps of the renal access (puncture, guidewire application, dilation of the access tract, Amplatz sheath application) (Figures 11.2–11.6) may be corrected if needed, avoiding related complications due to wrong or insufficient insertion or overadvancement of the various devices; this would otherwise possibly cause hemorrhagic complications.
3) The creation of the water path around staghorn stones impacted within a calyx by means of the retrograde irrigation facilitates the insertion of the hydrophilic guidewire, and supports the choice of the technique of tract dilation and of the size of the access tract. In absence of space between stone and mucosa no tapered dilators like balloon or silicon dilators (requiring a space of at least 1 cm within the calyx to host their tip) may be smoothly applied, but Alken dilators (requiring no other space than that sufficient to host the ball-shaped tip of the first stylet) should be employed instead. If the infundibulum of the access calyx is thin and inelastic adapt your instruments to the patient, and not vice versa. Choose a miniaturized access and avoid breaking the infundibulum, which would cause unnecessary bleeding.
4) Stones in calyces which are difficult difficult to reach with either the rigid or the flexible nephroscope through the access tract can be treated (Figure 11.8b,c). The active contribution of the retrograde flexible ureteroscope in the stone management and treatment avoids the need for multiple percutaneous tracts [75–77], thus reducing the risk of bleeding and related complications [78].
5) Final retrieval of residual fragments in combination with the flexible nephroscope is feasible, either extracting them retrogradely or passing the ball through the Amplatz sheath (Figure 11.8c).

## Conclusion

Modern-day PCNL is very different from the initial 30 Fr rigid-only PCNL of the 1970s, having undergone considerable evolution, mainly driven by a variety of improvements in access techniques, endoscopic instrumentation technology, lithotripsy devices, and drainage management.

The introduction of the supine and supine-modified positions is also part of this evolution, enabling safer procedures from an anesthesiologic point of view, and an easily combined antegrade and retrograde surgery (ECIRS), allowing a thorough tailoring of the procedure to the patient and the urolithiasis. ECIRS has no obvious clinical superiority if compared to standard prone PCNL [79], but it is certainly a new, safe, and effective way of interpreting PCNL and is here to stay, having started to gain acceptance and popularity within the urological community [9, 11, 12].

Video 11.1 gives an overview of ECIRS.

## Acknowledgements

Dr. Manuela Ingrosso largely contributed to the editing of the surgical video describing ECIRS in the Galdakao-modified supine Valdivia position.

## Introduction

Positioning for percutaneous nephrolithotomy (PCNL) is an important, yet often neglected, aspect of the procedure. Operators invariably become wedded to one position, yet with knowledge and experience of other positions there is the freedom to choose the most appropriate technique for the case at hand. Since the introduction of percutaneous renal surgery for stone disease by Fernstrom and Johansson in 1976 [1] there has been a proliferation of case series addressing various modifications to patient positioning, including the lateral decubitus [2–4], modified lateral [5], reverse lithotomy [6], split-leg [7–9], and supine [10] positions. However, most of these have not gained widespread acceptance other than prone and, to a lesser extent, the supine positions. Today, PCNL is usually performed with the patient in the prone position. A recent survey of Endourological Society members found that 86% of respondents used the prone position, 10% supine, and 4% lateral decubitus [11]. We have previously described a prone-flexed modification that confers several advantages over the conventional prone technique [12].

In this chapter, we review in detail both the conventional prone technique as well as our prone-flexed modification. Additionally, we describe the lateral technique and our lateral-flexed modification technique, which we find particularly useful in morbidly obese patients and those with severe kyphoscoliosis. We have also attempted to provide an anatomic explanation for the known complications associated with PCNL, including the rare complications related to patient positioning, and how attention to patient positioning can mitigate these issues. Finally, we also provide an overview of the literature comparing prone to supine PCNL.

## Prone and prone-flexed positions

Due to the retroperitoneal location of the kidneys and their proximity to the flank, PCNL is most commonly performed in the prone position with straightforward access to the collecting system [11]. However, when the procedure was being developed in the early 1980s, direct calyceal puncture was not thought to be important, provided that puncture was along the avascular line of Brödel. It has since been recognized that puncture directly into a calyx provides the safest access for stone removal [13, 14]. At present, the majority of PCNLs are performed with the patient prone and access is obtained through a posterior or posterolateral calyx. This position confers numerous advantages, with the main disadvantages being the time required for patient repositioning and anesthetic concerns in the morbidly obese (Table 12.1). We have previously shown that the prone-flexed position, a simple modification to conventional prone positioning, has several additional advantages [12] and can be implemented on most operating room (OR) tables that permit fluoroscopy. Some OR tables may have to be reversed in order to produce adequate space for the C-arm image intensifier. This space is increased significantly by flexion of the table during prone-flexed PCNL.

### Percutaneous lithotomy in the prone and prone-flexed positions (see Video 12.1)

#### Retrograde pyelogram and choice of calyx

To perform fluoroscopically guided access, a high-quality retrograde pyelogram is essential. Consequently, we begin all procedures with the patient positioned supine. Once the patient has been intubated under general anesthesia, and the genitalia prepped with providone-iodine,

**Table 12.1** Patient repositioning to and from prone adds to OR time.

| | Technique | Advantages | Disadvantages |
|---|---|---|---|
| Prone | Patient is prone with a padded bolster under the upper thorax to facilitate ventilation | Large field with wide choice of calyces for access<br>Easy end-on access to the posterior calyces<br>Easiest access to upper pole<br>Wide space for instrument manipulation<br>Renal pelvis is dependent with easier access to mobile stones<br>Optimal position for fluoroscopically guided access (bullseye or triangulation)<br>Minimal interference from the OR table | Patient repositioning from prone adds to OR time<br>May have difficulty with ventilation in obese patients<br>Risk of respiratory or cardiovascular compromise<br>Theoretical risk of ocular complications |
| Prone-flexed | Patient is prone, with a padded bolster under the upper thorax to facilitate ventilation<br>Flexed at the waist 30–40°<br>Knees are flexed 15–20° | Similar advantages to prone position<br>Further increased working space<br>Flattening the lumbar lordosis decreases instrument conflicts with buttock<br>May convert supra-11th to supra-12th or supra-12th to infracostal access by displacing the kidneys caudally<br>Reduces skin to stone distance<br>Reduces chance of spleen or liver injury | Similar disadvantages to prone position<br>Extra padding needed due to head-down position<br>May increase airway pressures |
| Prone split-leg | Patient prone, with the genitalia at the bottom of the OR table<br>Legs on padded adaptors and abducted up to 45° | Similar advantages to prone position<br>May perform ureteroscopy without patient repositioning or fear of contaminating instruments<br>Allows endoscopic-guided access | Similar disadvantages to prone position<br>Patient is further down the OR table, away from the anesthesiologist<br>May be difficult to demonstrate posterior calyces especially with dilated calyces<br>May require endoscopic-guided access |

flexible cystoscopy is performed. In men, this is performed with the patient supine, while the frog-leg position is useful in women. A 5 Fr Flextip (Cook Medical) ureteral catheter with a terminal side hole, which facilitates aspiration, is passed into the collecting system. Urine is completely aspirated and replaced with radiographic contrast to identify all calyces. Urine is less dense than contrast and, as a result, any urine left within the collecting system will tend to collect at the highest point within the kidney and float on top of the contrast. This property can be helpful to the surgeon when distinguishing anterior and posterior calyces. In the supine position, posterior calyces are identified by the presence of denser contrast within them, while anterior calyces appear paler due to the mixture of contrast with urine. Conversely, when the patient is repositioned prone, posterior calyces often appear paler. If too much pure urine without contrast is present, these calyces may be poorly visualized or even invisible.

A C-arm image intensifier is used to examine the anatomy of the collecting system and the position of all stones. Four fluoroscopic images are captured: a scout image to identify all calculi, an anteroposterior (AP), and two obliques. These images help create a mental three-dimensional (3D) picture of the calyceal anatomy, and can be referred to during the procedure. In the anterolateral view, the posterior calyces are viewed from the side and appear longer, whereas in the anteromedial view, they are seen through the central axis of the kidney and are viewed end-on, appearing shorter (Figure 12.1).

A ureteral occlusion balloon (Cook Medical) is then inserted over a guidewire, positioned at the ureteropelvic junction. A three-way valve is attached and connected to a 10 ml syringe and intravenous tubing leading to a bottle of contrast. This allows aspiration and infusion of additional contrast as needed during the case. Using an occlusion balloon has several benefits. First, the balloon prevents stone fragments from falling into the ureter. Second, the constant pressure of contrast in the renal collecting system ensures a persistent pyelogram, facilitating calyx identification when the patient is repositioned prone. Third, flow of contrast under gravity distends the collecting system, providing a larger target for access. Fourth, free return of contrast out through the needle allows the surgeon to rapidly confirm successful puncture of the chosen calyx. Finally, the occlusion balloon is secured externally to a Foley catheter using a Tegaderm™ (3 M) to allow for easy

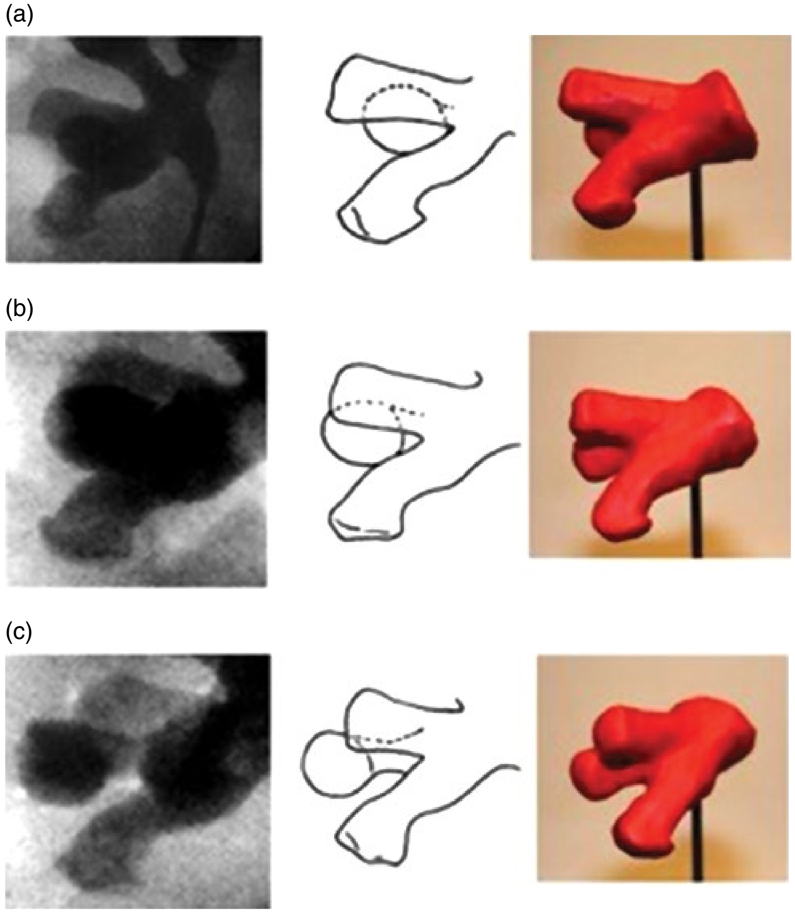

**Figure 12.1** 3D model of the lower pole renal collecting system of the right kidney with the patient in supine position. The posterior calyx is dependent, filling with dense contrast. Anterior calyces are paler due to the mixture of contrast with less dense urine. (a) With the C-arm rotated 30° toward the left side of the patient, the posterior calyx is viewed end-on and appears shorter. (b) Anteroposterior (AP) view. separation, and wrapped in sterile towels where is exits from the urethra, allowing for sterile insertion of a double J stent on a tether in a retrograde fashion at the end of the procedure.

## Renal puncture and dilation of the tract

With a Foley catheter *in situ* and the ureteral occlusion balloon secured externally, we reposition the patient prone with the assistance of additional staff members. Generous padding is placed under the knees, feet, and chest to prevent pressure injury and to facilitate ventilation (Figure 12.2). The eyes are taped to prevent corneal abrasions and the head is placed in a prone position foam headrest with cut-out holes for the eyes, nose, and endotracheal tube. We have found that there is no one support that is universally appropriate for all patients, so several options are available at all times. In the prone position there tends to be hyperextension of the cervical spine but with flexion in the prone-flexed position the head drops forward and reverses this hyperextension. To prevent brachial plexus injury, the arms should be kept below the level of the chest, and are both externally rotated at the shoulder, and flexed at the elbow. Again, generous padding is utilized. Finally, a safety strap is placed across the buttocks.

In the prone position, the natural, anterior lordosis of the spine is exaggerated. This complicates access by compressing the working space and leads to instrument conflicts with the buttocks. To avoid this, the table can be flexed 30–40° at the level of the lower abdomen (Figure 12.2) to open the space between the 12th rib and the posterior iliac crest (Figure 12.3). Flexion of the hips not only increases the working space on the patient's flank [15], but also may rotate the ribs cephalad, further increasing the working space and, along with caudal displacement of the kidneys in this position, often converting a supracostal to an infracostal access or a supra-11th rib to a supra-12th rib access [12]. Wide skin preparation is performed from above the 10th rib to the buttocks and medially from the spinous process to the mid-axillary line, laterally. We use chlorhexidine-alcohol as it was shown to be superior to povidone-iodine at preventing surgical site infections in the perioperative period in a multicenter randomized controlled trial (RCT) [16]. Due to the copious amount of irrigation necessary for PCNL, we use an adhesive neurosurgical drape with a drainage pouch connected to suction to direct fluid away from the

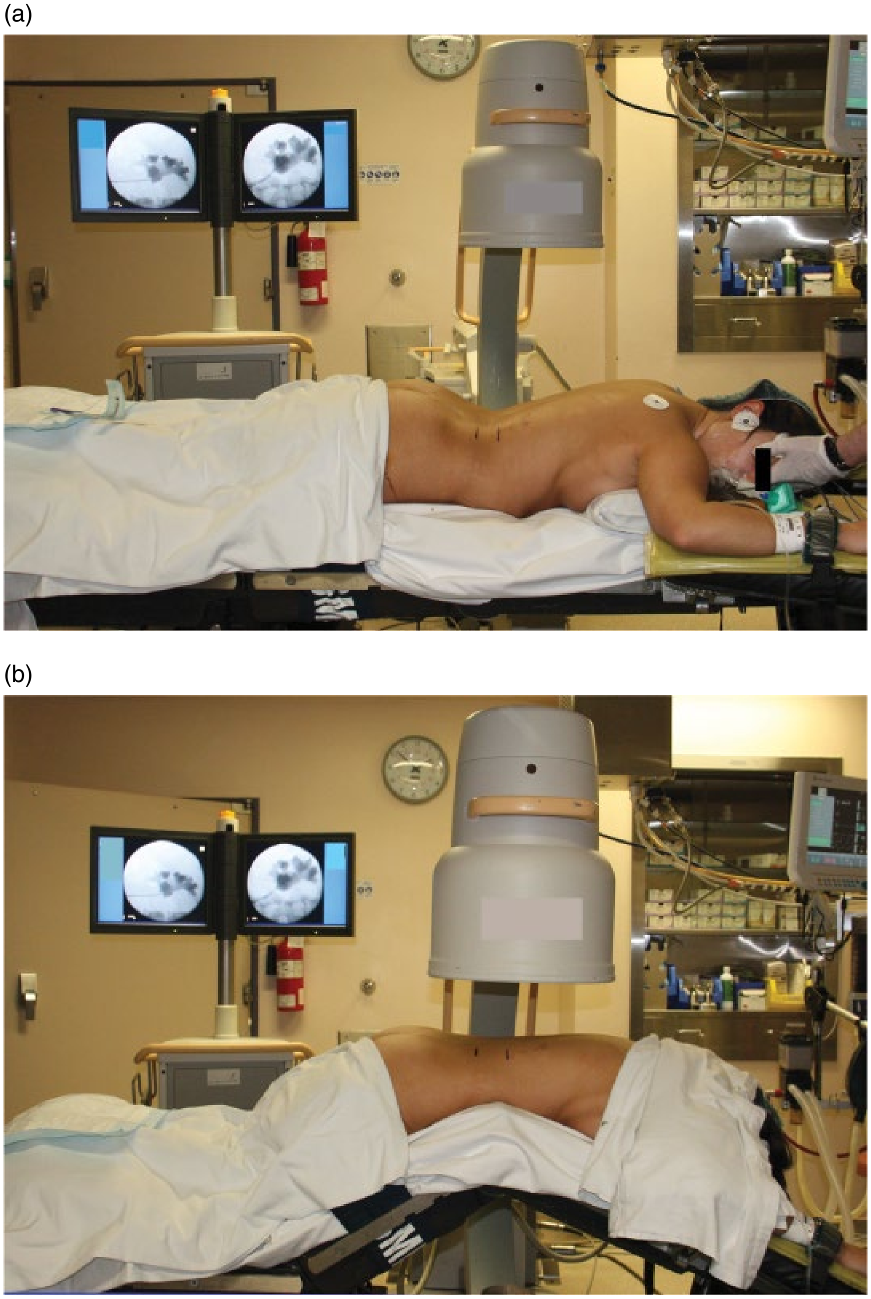

**Figure 12.2** Configuration of OR table with padding and C-arm [96]. Reproduced with permission of John Wiley and Sons.

patient. Only normal saline irrigation is used unless electrocautery is required, when it is changed to a nonelectrolyte solution. To prevent hypothermia, all irrigation fluid is heated to 42 °C in a warming cabinet.

### Bullseye technique

The C-arm is draped and used to identify the previously chosen posterior or posterior-lateral calyx. Due to the change to the prone position, the posterior calyces are now less dense as the heavier contrast flows anteriorly (Figure 12.4). We favor a conventional bullseye technique for performing renal puncture in the prone position; however, a triangulation technique can also be used. Both methods are described in this chapter. Prone and prone-flexed positioning allows maximal excursion of the C-arm around the OR table, giving the widest possible unobstructed imaging windows. Flexing the table in the prone-flexed position significantly increases the space below the table to allow movement of the C-arm. In the prone position, the posterior calyces move in the

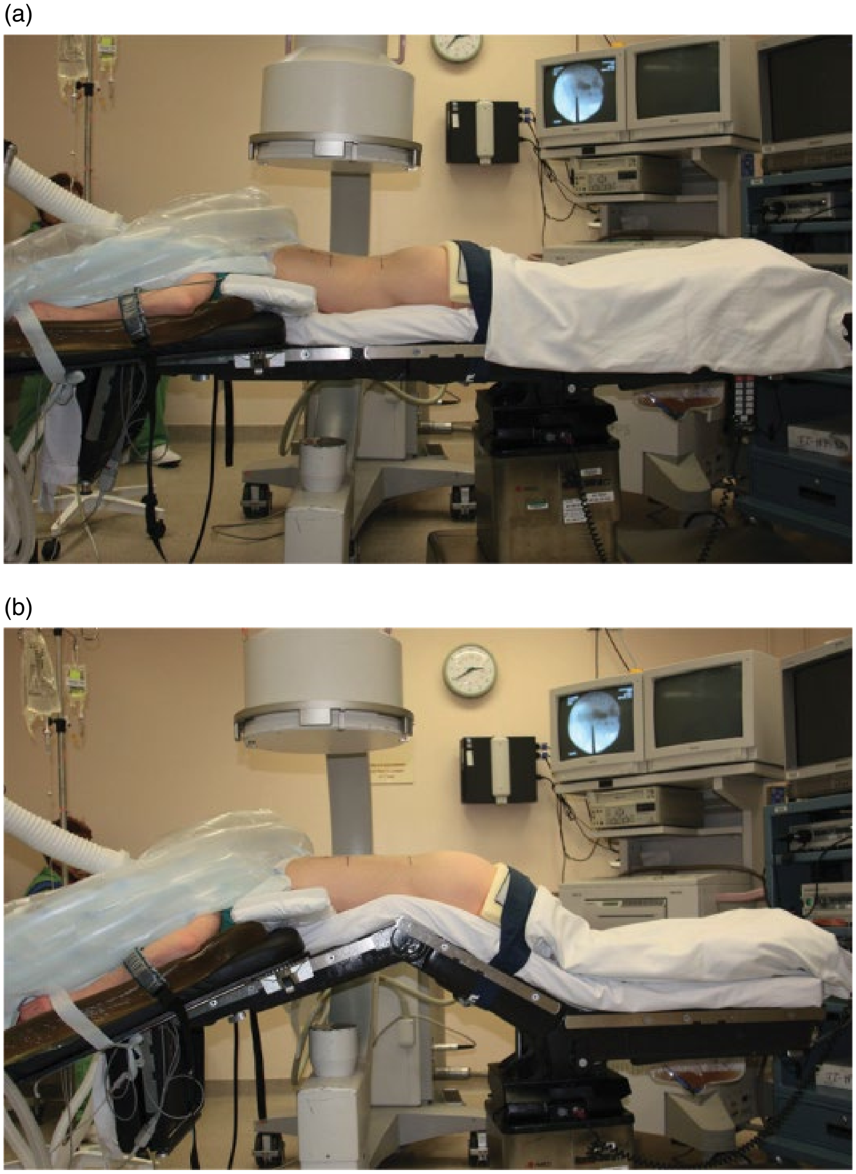

**Figure 12.3** (a) Prone and (b) prone-flexed patient positions. A padded support is placed under the patient's chest to improve respiration. With the OR table flexed 30–40°, the patient's flank is flattened and there is increased area available for puncture. Note also that prone-flexed positioning decreases obstruction from the buttocks with lower pole access.

opposite direction to the image intensifier of the C-arm (Figure 12.4). With the C-arm rotated 30° from the vertical, towards the operator, the posterior calyces move away, and shorten as one looks down the axis of the infundibulum. Using the bullseye technique, in this position, the calyx of choice is viewed end-on. We use an 18G Trocar needle to puncture the calyx in the center of the papilla. This needle lacks a beveled edge and, as such, resists deflection away from the axis of puncture. The needle is inserted and advanced along the line of the X-ray beam. To assess the depth of the needle, the C-arm is periodically rotated away from the operator (Figure 12.4). To minimize radiation exposure to the surgeon's hands, the needle can be held in a long Kelly forceps, aligned with the calyx under fluoroscopy, and advanced during expiration without fluoroscopy. Once the calyx is entered, and a free flow of contrast obtained, an Amplatz extra-stiff or super-stiff guidewire is passed down the needle into the collecting system.

Due to the presence of the occlusion balloon, we do not attempt to pass the guidewire down the ureter, although this may occur. A small depth-gauge ring on the needle is adjusted to skin level to mark the depth between the skin and the collecting system. Knowledge

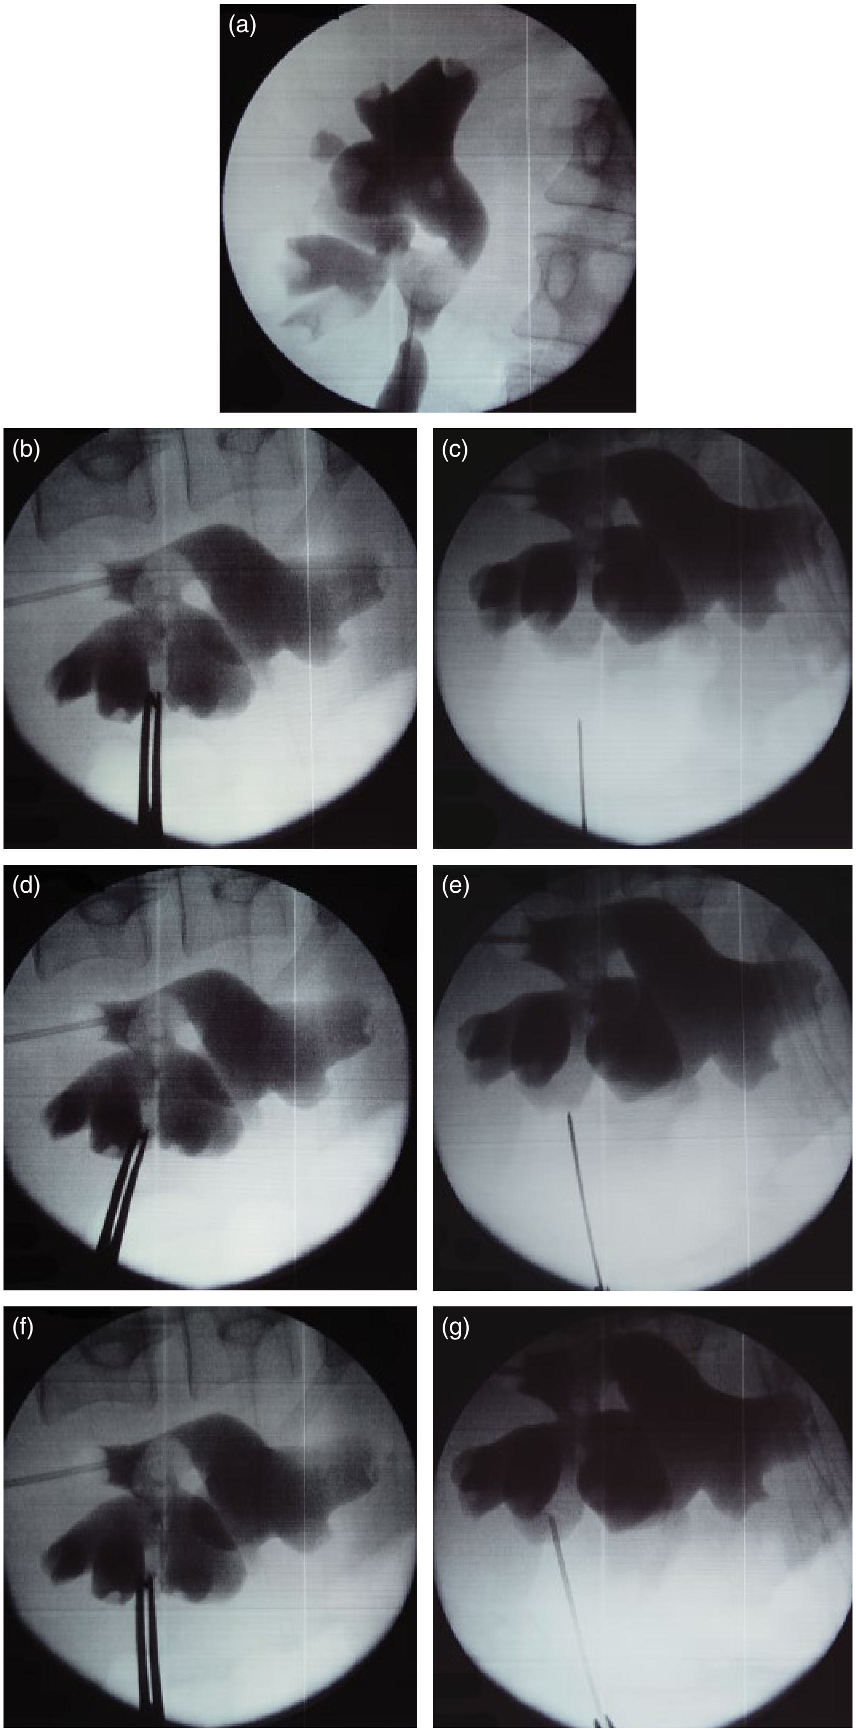

**Figure 12.4** Bullseye technique. (a) AP view with the patient in the supine position. All subsequent images are with the patient in the prone-flexed position. (b) AP view with the forceps holding the needle and aimed at the chosen posterior calyx. (c) 30° oblique view demonstrating the depth required for puncture. (d) AP bullseye view. of this measurement reduces radiation exposure during insertion of the fascial dilators and nephrostomy tract dilating balloon. Fascial dilators (6, 8, and 10 F) are used to dilate the tract and then a safety guidewire can be inserted using a 10 Fr dual-lumen catheter (Cook Medical). The tract is then further dilated to 30 Fr with a nephrostomy tract dilating balloon (Cook Medical) over which a 34 Fr Amplatz sheath with a 30 Fr inner diameter is passed. Although different methods of tract dilation exist, including balloons, Amplatz serial dilators, and the Alken telescopic dilator among others, we favor balloon dilation. We have found this to be both quick and atraumatic, although this comes at increased cost.

## Adjuncts to assist with patient positioning

The prone-flexed modification can add several advantages to the operating surgeon without any impediment to C-arm movement. Adopting this position on an OR table without a flex option is still possible through the use of bolsters. The "Montreal mattress" is a preshaped surgical bolster that can be used as an adjunct for the support of prone patients [17]. The advantage of this device is the central cavity which allows for free movement of the abdomen. Theoretically, this should lessen respiratory compromise and minimize cardiovascular effects such as inferior vena cava obstruction. Another option is the radiolucent Wilson frame, an adjunct used by spinal surgeons to mimic the prone-flexed position on a standard OR table. Its advantages include the ability to control the degree of flexion required as well as to use adjustable contour pads that allow for free excursion of the abdomen, preventing respiratory compromise. The main limitation to its use is the reduction in depth, preventing C-arm movement, instrument manipulation, the working space within the C-arm, and a reduction in magnification.

## Advantages and disadvantages of the prone and prone-flexed positions

As mentioned, the majority of PCNLs are still carried out with the patient in the prone position, with prior retrograde placement of a ureteral catheter or occlusion balloon under fluoroscopic control. This initial procedure can be performed with the patient either supine or prone. If performed while the patient is supine, it is necessary to position and drape the patient twice, prolonging OR time [18, 19]. By commencing the procedure with the patient in the prone position immediately following induction of general anesthesia, the patient will still require repositioning, but is draped only once [17]. A split-leg modification can facilitate access to the external genitalia, for simultaneous antegrade and retrograde approaches [7, 8, 20]. In the prone position it may be difficult to access the anteriorly displaced ureteric orifices for the retrograde study, but with practice this can become routine. Additionally, if the procedure is started in the prone position, identification of the posterior calyces, especially in obstructed systems, may be difficult, or impossible. The presence of pure urine within the collecting system, especially if dilated, may result in urine floating on top of the denser contrast and render them invisible. For this reason, it is our preference to begin the procedure with the patient supine where the dense contrast sinks down into the posterior calyces.

Prone positioning for PCNL allows access to the entire flank, with a wide choice of access sites, especially when multiple accesses are required. Although still possible in the supine position, upper pole access is significantly easier when the patient is prone. An upper pole puncture has many advantages, including the ability to work down the renal axis, with minimal torque, as the more mobile lower pole rotates to align with the nephroscope. This reduces the chance of renal parenchymal shear and bleeding. Selection of an upper pole calyx is indicated in obese patients, as the upper pole is closer to the posterior abdominal wall than the lower pole. It is also indicated in patients with staghorn calculi, or stones in a horseshoe kidney, and facilitates access to multiple lower pole calyces with a single tract. In contrast, from the lower pole, visualization of the upper calyces with a rigid nephroscope is rarely possible. Finally, dilation into the upper pole is easier due to more adherent attachments to Gerota's fascia limiting renal mobility, whereas the more mobile lower pole may move away from the operator during dilation and kink the guidewire. Despite these advantages, many authors still prefer a lower pole puncture with the reassurance that this approach will avoid thoracic complications. In our series, with a supracostal puncture, pleural complications occurred in 2.6% of patients [15].

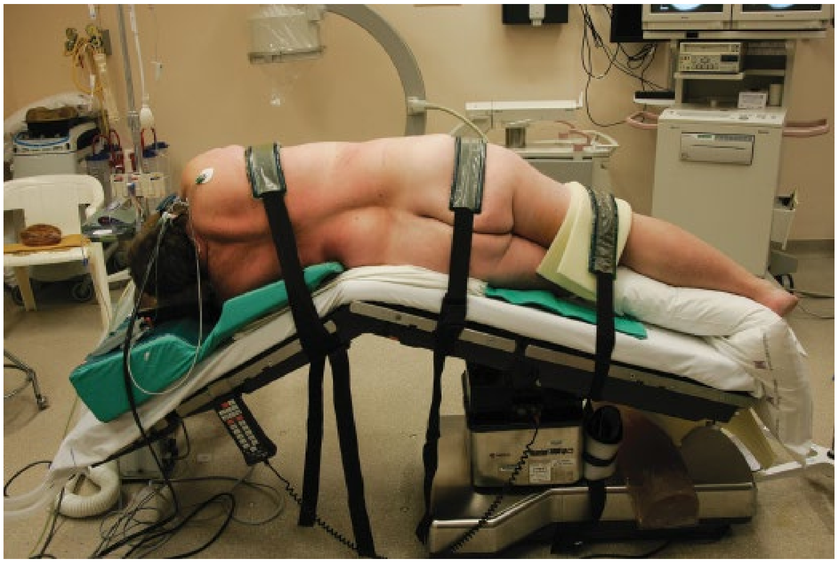
The prone-flexed modification that we describe provides several additional advantages over the traditional technique. First, and most obviously, the working space is further increased as the flank is significantly flattened, eliminating interference from the buttock during rigid nephroscopy through a lower pole tract (Figure 12.2) [12]. In addition, we have also shown that when in this position, the spleen is displaced medially and the kidneys are displaced inferiorly in the retroperitoneum [12]. This effect is most pronounced with the left kidney, which is lower than the right kidney in greater than 90% of cases. Also, due to this modification, with this displacement, a supra-11th rib access may be converted to a supra-12th rib, or a supra-12th to an infracostal access. Finally, the flank is significantly flattened, eliminating interference from the buttock during rigid nephroscopy through a lower pole tract [10].

## Lateral and lateral-flexed positions

Although the prone-flexed position for PCNL can be used for the obese patient, the lateral position has multiple advantages in these patients, and is sometimes the only feasible position for the morbidly obese patient with a body mass index (BMI) in excess of 50 kg/m$^2$ who cannot be ventilated prone or those with skeletal deformities, especially severe kyphoscoliosis. This position allows the protuberant abdomen and pannus to fall medially, taking the weight off the anterior abdominal wall as occurs when the patient is supine (Figure 12.5). This maximizes diaphragmatic excursion and facilitates general anesthesia. The pannus can also be supported separately if required.

The lateral-flexed position is familiar to any urologist who performs open and laparoscopic renal surgery. This position significantly widens the space between the 12th rib and the iliac crest, flattening the folds of adipose tissue and facilitating percutaneous access (Figure 12.6). The increased distance between the 12th rib and iliac crest, produced by this flexion, is even more pronounced than

(a)



(b)

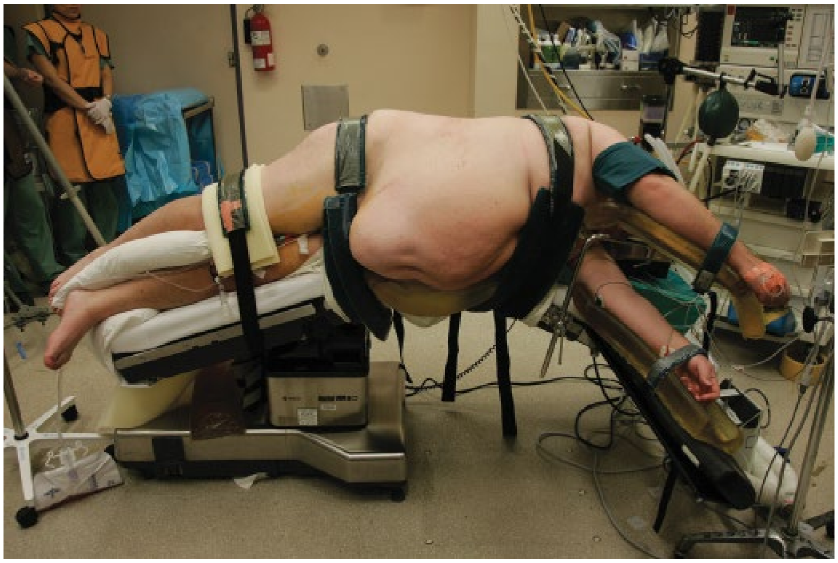


**Figure 12.5** Lateral-flexed patient position. (a) Posterior view. A wedge with a groove for the dependent arm is placed under the patient's torso. (b) Anterior view. Both arms are supported and flexed slightly at the elbow. Generous padding is used to prevent injury. Note that the pannus falls away from the patient, preventing respiratory compromise.

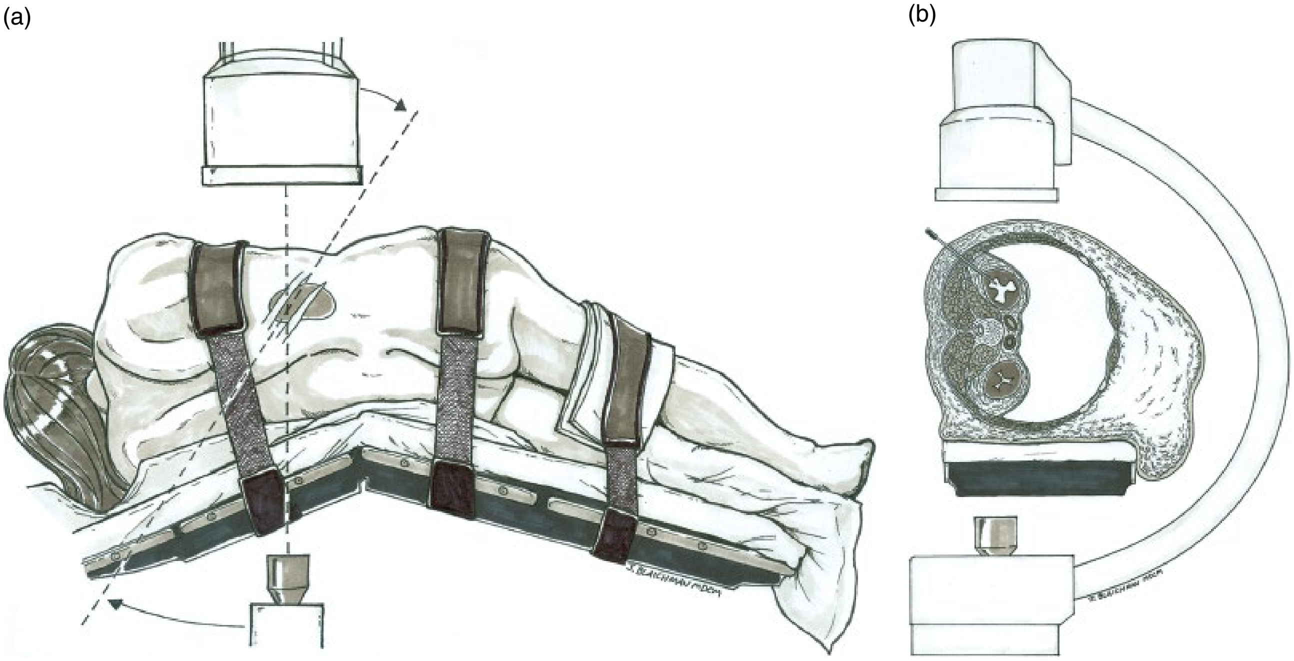

**Figure 12.6** (a) The C-arm is seen both vertical and in the oblique plane (angulated towards the feet), used for the triangulation technique, as described in the text. (b) A cross-sectional illustration, with the C-arm image intensifier positioned for the vertical anterioposterior view [96]. Reproduced with permission of John Wiley and Sons.

the increase produced by flexion with the patient prone. This also elevates the thoracic cage in relation to the kidney on that side and reduces the need for supracostal access. Also, in this position, the relative lack of adipose tissue over the costovertebral angle is frequently surprising in these morbidly obese patients and, provided the upper pole calyx is chosen for access, it is frequently possible to use a standard-length Amplatz sheath and nephroscope.

One disadvantage to flank positioning is that percutaneous access usually requires either ultrasound guidance or use of triangulation when using the C-arm image intensifier, as opposed to the standard bullseye technique. This is partly because of the restricted arc of rotation of most C-arms, but also because the metal side rails of most radiolucent tables prevent adequate visualization of the collecting system when the C-arm is rotated to an exaggerated position. A randomized study comparing access using ultrasound in the lateral-flexed position to fluoroscopy in the prone position achieved successful access in all cases ($n = 60$) with no difference in intraoperative bleeding but took longer (14.5 vs. 9.4 minutes for prone with fluoroscopy) [4]. Advantages of the lateral and lateral-flexed positions are outlined in Table 12.2.

## PCNL in the lateral and lateral-flexed positions (see Video 12.2)

As with prone or prone-flexed PCNL, the procedure begins with a retrograde pyelogram and insertion of a ureteral occlusion balloon. This is performed with the patient supine in order to choose the most appropriate calyx, as described earlier (Figure 12.7). In the lateral-flexed position the arms and legs are positioned as for open or laparoscopic renal surgery, and the patient is secured to the table with padded straps or tape over the upper chest and pelvis (Figure 12.5). An axillary roll or padded wedge with a groove to accommodate the dependent arm must be positioned to adequately support the chest and prevent positioning-related injury. Extra padding must also be placed under the dependent knee and ankle to prevent pressure-related complications.

The concept of triangulation is illustrated in Figures 12.8 and 12.9. With the C-arm in the AP configuration, it is possible to determine the cephalad–caudal axis direction for puncture. Oblique views are then similarly used to determine the AP direction of puncture. In this view, dropping the hand holding the needle to direct the needle laterally toward the anteroaxillary line will target the more anterior part of the kidney. Elevating the hand holding the needle will direct the needle toward the spine and will aim it toward the more posterior part of the kidney.

With the patient in the lateral position and the C-arm image intensifier placed on the abdominal side of the patient, the pelvicalyceal system is initially viewed in the AP position from above. The previously chosen calyx can be identified facing posteriorly towards the operator

**Table 12.2** Options for lateral patient positioning.

| | Technique | Advantages | Disadvantages |
|---|---|---|---|
| Lateral | Patient in lateral decubitus with no break in the OR table | Familiar to urologists who perform open renal surgery<br>Compared with prone, easier patient repositioning from supine<br>Easiest identification of the posterior calyces<br>Useful in morbid obesity or severe kyphoscoliosis<br>Least effect on cardiac and respiratory function<br>May be performed under epidural or local anesthesia alone<br>Renal pelvis is dependent with easier access to mobile stones<br>More ergonomic for the surgeon than prone position<br>May perform nephroscopy and ureteroscopy simultaneously | Patient repositioning is required<br>Fluoroscopy is technically limited necessitating triangulation or ultrasound-guided access |
| Lateral-flexed | Patient in lateral decubitus with 30–40° break in the OR table | Similar advantages to lateral position<br>Significantly increased working space<br>Reduces flank fat in morbidly obese patients<br>May elevate the lower ribs, reducing the need for supracostal access | Similar disadvantages to lateral position |
| Modified lateral "Barts technique" | Patient in lithotomy with ipsilateral pelvis elevated 45°<br>Shoulders rotated to be perpendicular to the OR table<br>Ipsilateral leg is flexed and adducted, contralateral leg is fully abducted | May perform nephroscopy and ureteroscopy without patient repositioning<br>Fewer cardiovascular and respiratory effects than prone<br>Improved access to flank compared to supine | Requires significant patient mobility<br>Not suitable for patients with musculoskeletal deformities<br>Fluoroscopy is technically limited, as with lateral |

(Figure 12.10). The line of access can then be chosen. This can be the shortest distance, at right angles to the back, or can be slightly oblique in order to work more along the axis of the kidney, angling up into a lower pole calyx or angling down into an upper calyx. The site of actual puncture is made two finger breadths lateral to the edge of the paraspinal muscles. If necessary, the site that was initially chosen may be adjusted either cephalad or caudad if a rib is in the line of the needle tract. The needle is held in a Kelly clamp and then advanced with fluoroscopic monitoring. With the C-arm vertical or rotated 10–20° towards the X-ray machine, to lengthen the calyx, the needle is angled in a caudal or cranial direction to point directly at the calyx (Figure 12.10). Holding this angle steady, the C-arm is swung with the intensifier towards the foot of the table looking up towards the lower pole of the kidney. This gives more of a lateral rather than AP view of the needle. The AP direction of the needle is then adjusted to again point directly at the chosen calyx. The needle is then advanced along this line, checking both angles at regular intervals until the calyx is punctured. The stylette is removed and contrast should flow freely from the needle.

## Special situations

### Morbid obesity

PCNL in the morbidly obese patient with a BMI greater than 40 kg/m$^2$ poses a challenge for both the operating surgeon and the anesthesiologist. From a surgical perspective, there are several aspects that must be considered. First, achieving satisfactory X-ray penetration can be problematic with older fluoroscopic units, making targeting difficult. Second, anatomic landmarks are also obscured and can make tract placement difficult. This can be especially problematic for upper pole punctures.

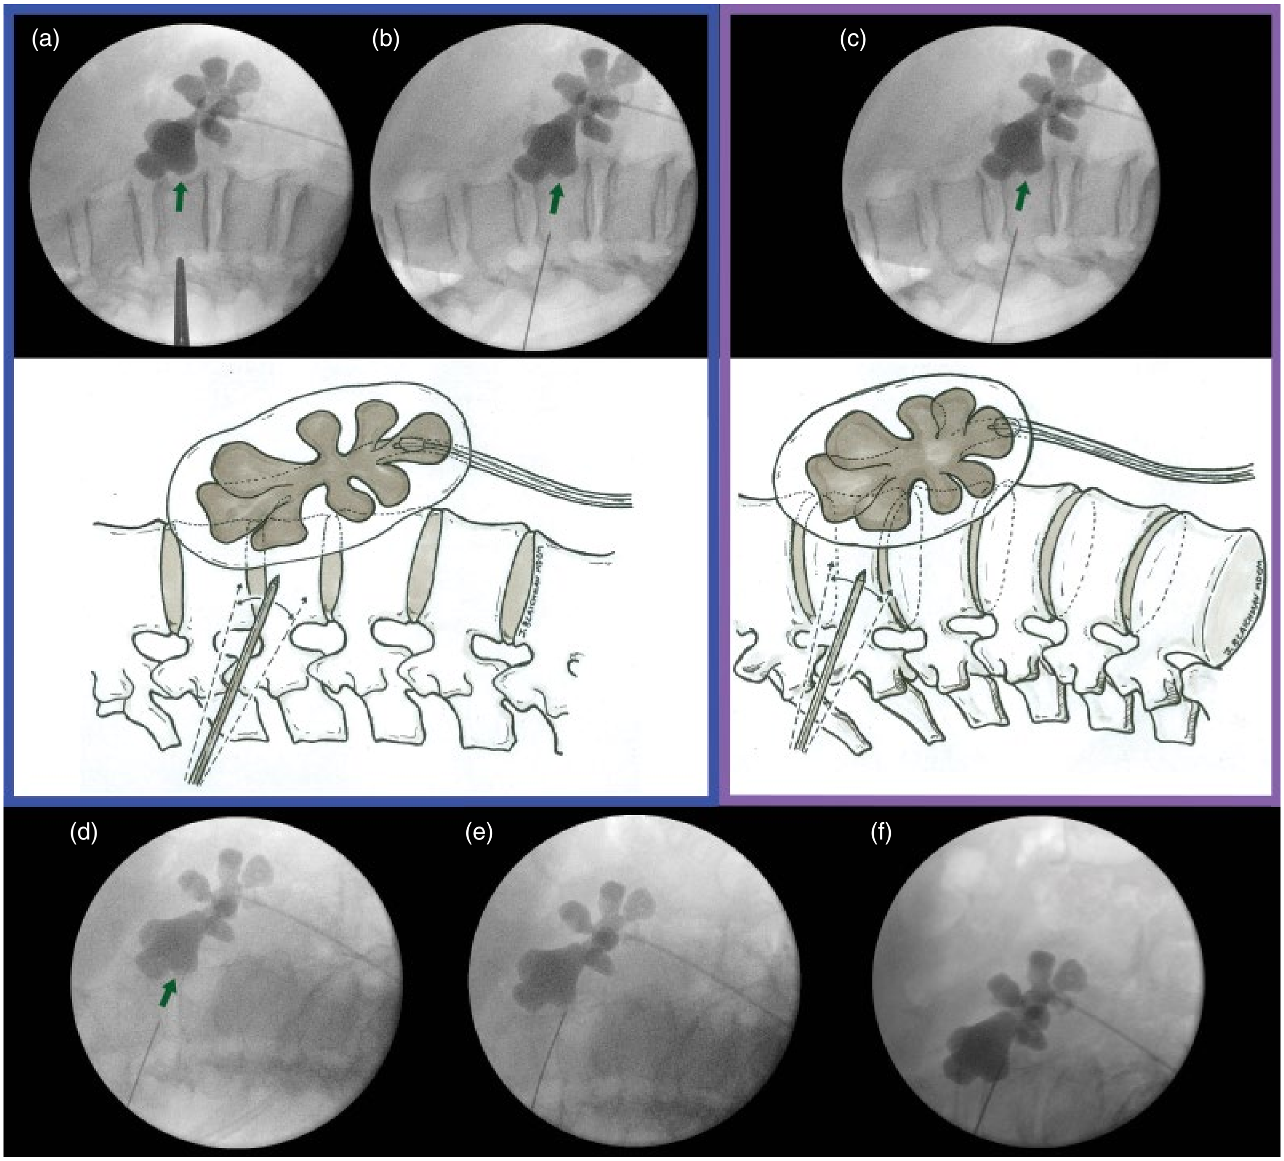

**Figure 12.7** Triangulation fluoroscopic technique in the lateral-flexed position for access into a posterior calyx. (a) The C-arm is initially positioned vertically, perpendicular to the floor. With the calyces distended with contrast, the posterior calyx previously chosen for puncture is identified and the calyx is directed towards the surgeon. A point on the skin, one to two finger breadths lateral to the paraspinal muscles and in line with the calyx in the cephalad–caudal plane, is chosen. In this fluoroscopic image, the targeted calyx is indicated with an arrow. (b) This site can be moved more cephalad or caudal if a rib is in the way, or to angle the tract superiorly into a lower pole calyx. In this case, the skin puncture site was moved more cephalad since the chosen point was over the rib. The needle is inserted and aimed directly at the chosen calyx under fluoroscopy with the C-arm vertical, as shown in (a) and (b). Movement of the hand in the cranial–caudal plane will move the needle in the left-right plane as shown in the illustration. (c) Once the needle has been inserted 2–3 cm, the C-arm is rotated obliquely towards the feet so the X-ray beam penetrates at a 45° angle to the initial view. This gives a side view of the needle, rather than an AP view from above. When the needle is viewed from the side (illustration), elevation (towards the ceiling) or lowering (towards the floor) of the hand holding the needle will adjust its tip in the AP plane, relative to the kidney. With the needle angle adjusted to aim directly at the calyx, the needle is advanced. (d) The C-arm is then rotated to the original vertical position to ensure the needle is still directed towards the calyx in this plane. (e) The needle is advanced in a stepwise fashion during expiration, checking the direction in the two planes until the calyx is entered. Here, seen in the oblique plane, the needle is about to enter the calyx. (f) Oblique view with the needle in the chosen calyx [96]. Reproduced with permission of John Wiley and Sons.

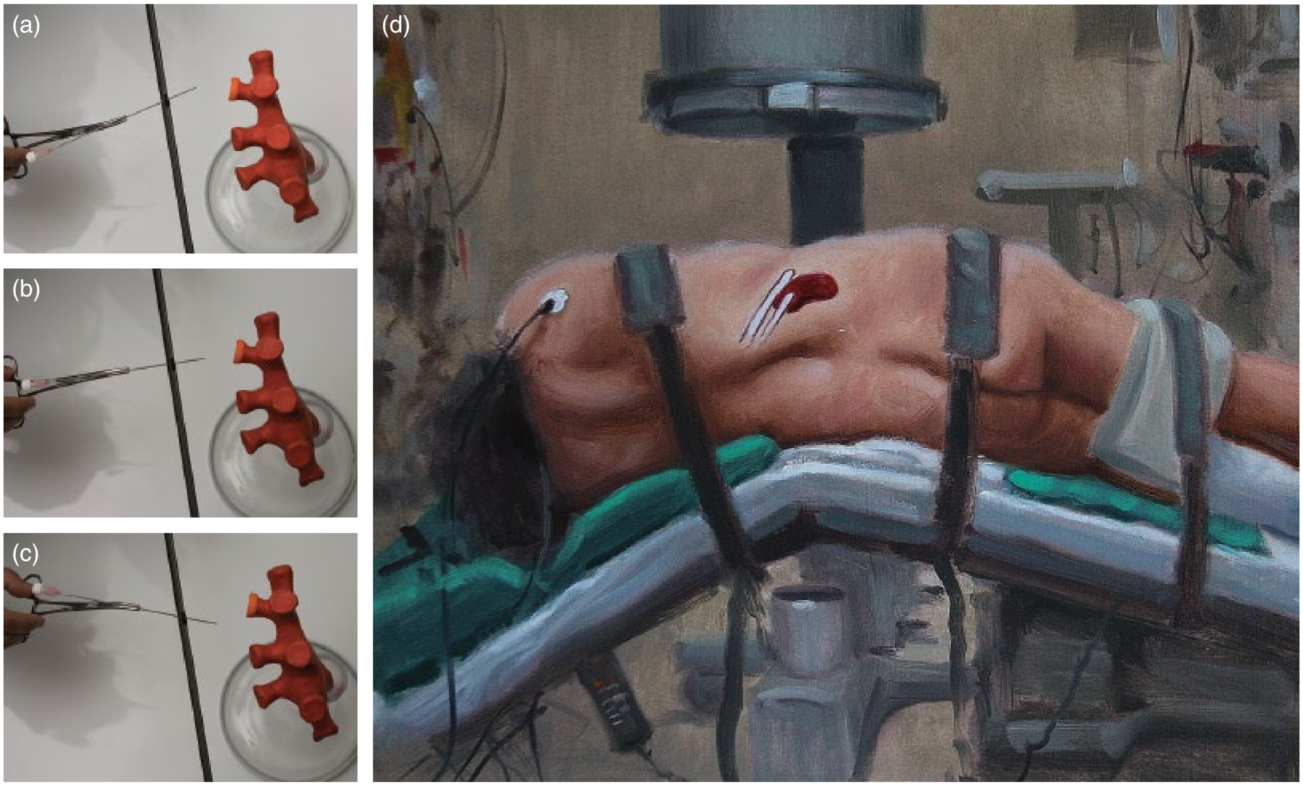

**Figure 12.8** AP views with the patient in the lateral-flexed position. In this demonstration, the target is an upper pole, posterior calyx, viewed from directly above. The chosen calyx is seen from the side, facing posteriorly. (a) Needle is aiming too cephalad to the target calyx. (b) Needle will have direct entry into the papilla of the desired calyx. (c) Needle is aiming too caudal to the target. (d) Illustration depicting the position of the C-arm necessary to obtain this view.

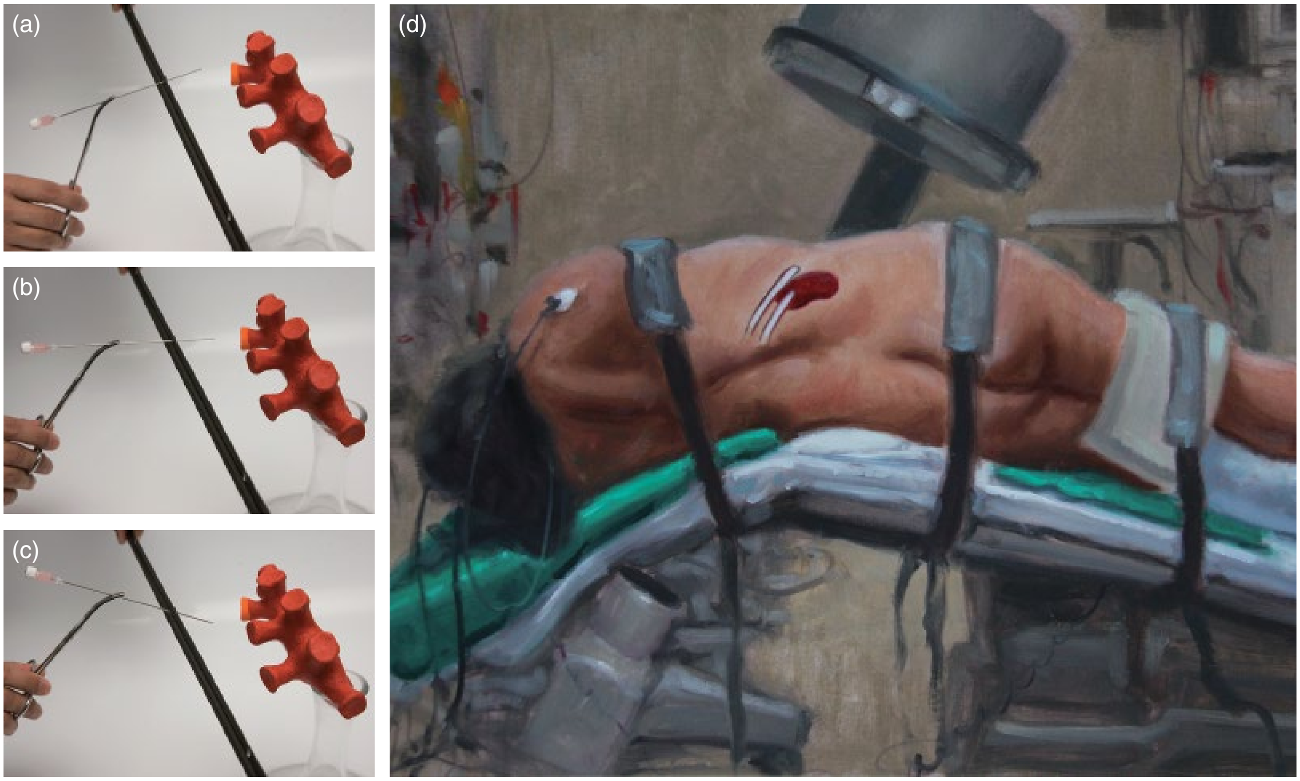

**Figure 12.9** Oblique views with the patient in the lateral-flexed position. With the C-arm offset approximately 30° towards the feet, the targeted posterior, upper pole calyx is identified. (a) Needle is aiming too far anterior to the target calyx. (b) Needle will have direct entry into the papilla of the desired calyx. (c) Needle is aiming too far posterior to the target. (d) Illustration depicting the position of the C-arm necessary to obtain this view.

(b) Point of entry chosen with forceps marking point lateral to the paraspinal muscles in line with the targeted calyx. (c) AP view with the needle along the chosen path. (d) Oblique view with the needle pointing to the chosen calyx. (e) AP view with the needle approaching the calyx. (f) Oblique view with the needle on target, approaching the calyx. (g) AP view with the needle in the chosen calyx. (h) Oblique view with the needle in the chosen calyx.

Third, the depth of the tract is significantly increased and often requires extra-long instruments, including a sheath and rigid endoscopes. A subset analysis of the Clinical Research Office of the Endourology Society (CROES) PCNL Global study demonstrated that overall stone-free rates are decreased with obesity, with no difference in transfusion or overall complication rate [21]. Surprisingly, despite the increased complexity of these cases and the poor fluoroscopic image quality obtained when using the C-arm to search for small residual fragments, several authors have independently demonstrated that stone-free rates appear to be unaffected when PCNL outcomes are stratified by BMI [22–26].

In terms of patient positioning, the lateral-flexed position seems ideally suited for this clinical situation, with the benefits explained in detail above (Table 12.2). Other authors have similarly used lateral positioning to overcome these difficulties. Kerbl et al. described in detail the use of lateral positioning to successfully treat two patients with a BMI greater than 50 kg/m$^2$. In these patients, it was noted that the supine position could not be tolerated due to respiratory difficulties [2]. Gofrit et al. echoed these concerns and similarly adopted the lateral decubitus position in patients with a BMI greater than 40 kg/m$^2$ [3]. In contrast, conventional prone positioning may still be well tolerated even at extremes of BMI and has been used by several authors for the morbidly obese, including patients with a BMI well over 50 kg/m$^2$ [24, 25, 27, 28]. In a series of 21 patients with BMI >50 kg/m$^2$, reported by Keheila et al., PCNL was performed in prone position without respiratory compromise [28]. The authors recommend several special considerations for PCNL in the super obese including using extra-long instruments, custom long sheaths with suture “tails,” choosing the shortest tract possible, and leaving in place a nephroureterostomy tube rather than a nephrostomy tube. The prone position may still be well tolerated even at extremes of BMI and may be useful when the weight of the patient is greater than the tolerance of the OR table, requiring the use of two tables in close proximity. Wu et al. described a technique of awake endotracheal intubation and prone self-positioning in a patient with a BMI of 51 kg/m$^2$ [27]. In a large series, El-Assmy et al. favored supine positioning for morbidly obese patients, but conceded that prone positioning was necessary in some cases [23]. Finally, Curtis et al. described using a larger skin incision to expose the fascia prior to performing puncture using in the prone position in a patient with a BMI of 55.5 kg/m$^2$ [29]. Their technique was to use a larger skin incision to expose the fascia prior to performing puncture. This technique has the potential of avoiding the need for an extra-long working sheath but can only be used with the patient in the prone or lateral decubitus positions.

## Kyphoscoliosis/musculoskeletal abnormalities

The treatment of patients with severe musculoskeletal abnormalities poses a particular challenge to the surgeon, and PCNL is no exception. In these patients, the loss of bony landmarks, distorted position of abdominal organs in relation to the target kidney, and difficulties with imaging secondary to X-ray penetration and interference from orthopedic hardware make PCNL difficult. To date, there is limited published data describing PCNL in the patient with severe kyphoscoliosis. Gofrit et al. described a single case of severe kyphosis preventing prone positioning. In this case, the lateral decubitus position provided good access to the flank. However, an upper pole nephrostomy had been placed in the radiology suite in advance of the procedure and was used to access the renal pelvic and lower pole calculi [3]. In the largest series of PCNL in patients with spinal deformities, Izol et al. described 16 patients who underwent PCNL with access gained by the treating urologist in the prone position including patients with kyphoscoliosis (five), post-polio syndrome (four), osteogenesis imperfecta (three), myotonic dystrophy (three), and ankylosing spondylitis (one) [30]. A high success rate (93.7%) and complication rate (31.2%) was reported, including transfusion (two), prolonged urine leak (one), infection (one), and nephrectomy (one). Matlaga et al. described a technique for computed tomography (CT)-guided access and included six patients with scoliosis in their dataset [31]. Anecdotally, we have used both prone and lateral positions for this population. No position is universally appropriate and adaptability is of paramount importance. Preoperative CT images must be examined carefully to identify when the fluoroscopic window, which is frequently limited, and access may require assistance of an interventional radiologist or a urologist trained in ultrasound-guided PCNL. Additionally, such patients will require additional padding as they can be prone to both pressure ulcers and nerve injuries.

## Renal anomalies

Renal anomalies create an increased level of complexity in the management of patients with stone disease. The CROES PCNL Global study had 202 patients with renal malformation including ectopic (26), horseshoe (102), and malrotation (74) [32]. Although treatment failure rates were higher in patients with renal anomalies (5% compared to 1.7% with normal renal anatomy), stone-free and complication rates were otherwise equal. In these patients, the prone position and upper pole punctures are preferred.

Urolithiasis in horseshoe kidneys is common, occurring with a reported incidence of 20–60% [33]. The accompanying rotational anomaly results in calyces that are oriented more posteriorly and a renal pelvis that is more anterior than in "normal" kidneys [34]. The lower pole is also oriented more medially and is fixed in the midline by the isthmus that connects it to the contralateral kidney. As a result, upper pole access is preferred as this provides the least angulation looking down the axis of the kidney, and minimizes torque when manipulating stones located in the renal pelvis and lower pole calyces. In the subset analysis of the CROES PCNL Global study, 87% of patients with a horseshoe kidney were treated in the prone position with 13% in supine [32]. When puncture is performed through the lower pole calyces, the tract is significantly longer and at a right angle to the renal axis. Consequently, with this access, viewing the upper pole may be difficult or even impossible with a rigid endoscope. Finally, the puncture site through the skin is often located more medially, when accessing the mid or lower calyces, and this can result in injuries to the segmental arteries. Together, all these factors favor PCNL for horseshoe kidneys in either the prone or lateral positions [35].

## Surgical tables for select positions

There are numerous surgical tables available for both general urology and endourologic procedures, and, as such, a review of each is beyond the scope of this chapter. However, the ideal table will be adaptable to the needs of both the patient and surgeon. For PCNL, an OR table should have a radiolucent, carbon-fiber top with narrow side rails for straps or arm rests. To allow the maximum number of positioning options, the table should also have the ability to flex and raise the legs, and have attachments for leg stirrups for the lithotomy and split-leg positions. It should also be possible to slide the table top towards the head or feet. From a technical perspective, the table should also be offset with a narrow base, allowing wide movement of the C-arm and a large imaging window. Finally, it should be possible to accommodate patients up to 270 kg.

The carbon-fiber table developed by Skytron incorporates many of these features. This table has been modified to confer multiple advantages to the endourologist performing renal access for PCNL [36]. Included among these are a large, unobstructed imaging window that can be used with a C-arm rotated in even the most extreme positions, as well as the ability to position the patient in lithotomy, allowing access to the perineum. One disadvantage of this table is the inability to flex the patient for the prone-flexed position.

## Anatomic considerations: renal axis and mobility

Knowledge of renal and retroperitoneal anatomy is essential to performing PCNL with minimal patient morbidity and a low risk of iatrogenic organ injury. The kidneys lie in the retroperitoneum with the psoas muscle lying posteromedially, which results in the long axis of the kidneys being deviated so that the upper pole is more medial in the coronal lane. The upper pole is also closer to the posterior abdominal wall and more densely attached to Gerota's fascia [37]. The lower pole is more anterior and freely mobile. These findings can easily be appreciated during open and laparoscopic renal surgery.

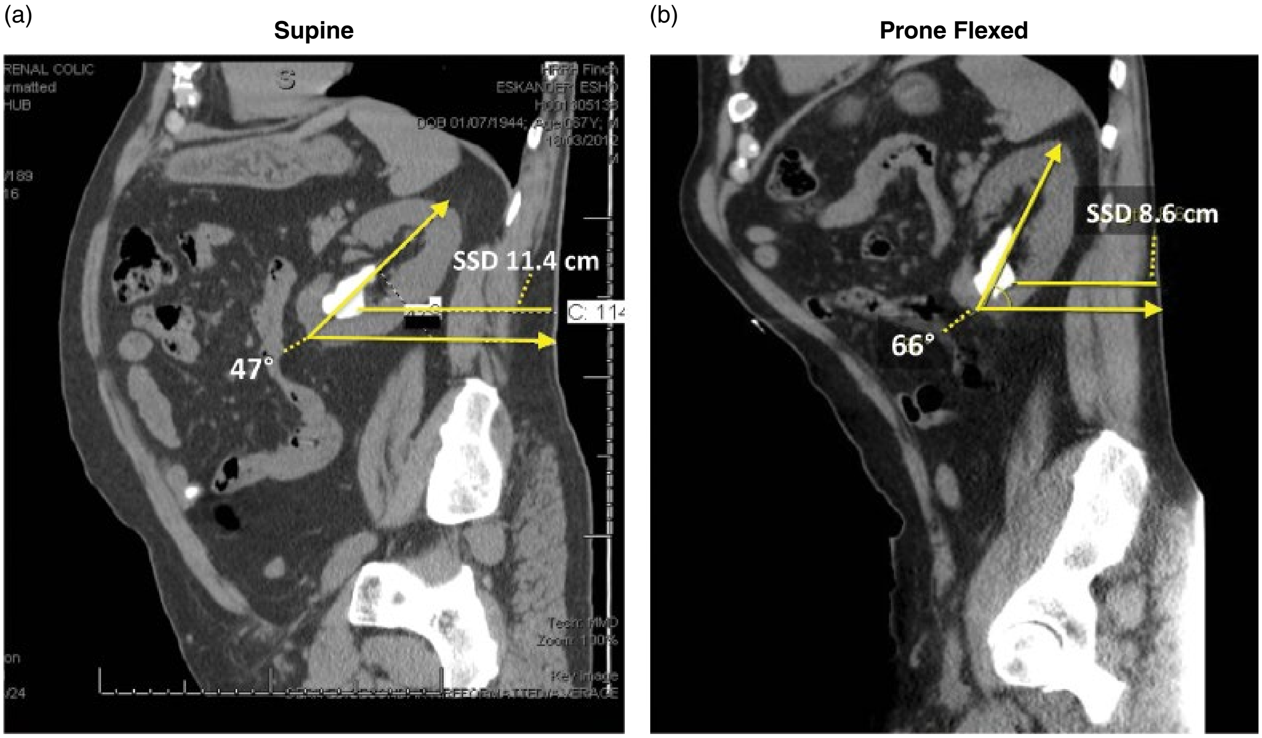
There are several implications to these findings. First, puncture of the lower pole may be slightly more difficult as the freely mobile lower pole tends to move away from the needle and dilators. Second, lower pole tracts tend to be longer and at a right angle to the axis of the kidney, making stone removal from upper calyces with rigid instruments more difficult. Compared to supine, the prone-flexed position shortens the distance from the skin to the upper and lower pole calyces and the renal angle is flattened, improving access to the upper pole through a lower pole puncture (Figure 12.11). Percutaneous access into the upper pole is simplified by the more dense attachments of Gerota's fascia, reducing mobility, and the shorter distance from the skin compared to into the lower pole.

## Complications of PCNL

Preventing and reducing complications of PCNL requires proper technique, adaptation, and attention to detail (see also Chapters 33–35). In our latest series of 318 consecutive PCNLs, our overall complication rate was 11.6% with no transfusions or angioembolizations [15]. This rate is lower than studies from a similar period published by de la Rosette et al. (37.2%) and Tefekeli et al. (29.2%) [38, 39].

### Intra-abodominal organ injury: colon, spleen, liver, and gallbladder

Several anatomic studies have attempted to define the relationship of organs to the target kidney and nephrostomy tract. However, the position of the kidneys within the retroperitoneum is dynamic, changing with both respiration and body position. We, and others, have demonstrated that when the patient is positioned in the prone or prone-flexed positions, the spleen and liver rotate laterally, away from the kidneys and nephrostomy tract, compared to when the patient is positioned supine [40, 41]. This would make it less likely that either of these organs would be injured with



- **Prone-flexed changes the renal angle, bringing lower pole closer to the skin (skin to stone distance SSD)**
- **Improves access to the lower pole**
- **Shortens the distance from the skin to the upper pole calyx**

**Figure 12.11** Sagittal CT reconstruction of the right kidney demonstrating puncture of upper and lower pole posterior calyces. Upper pole punctures are shorter and more in line with the ureteropelvic junction and renal pelvis, whereas lower pole punctures are longer and have more acute angles, leading to more torque and renal shear. (a) Supine and (b) prone-flexed positioning: this demonstrates how prone-flexed shortens the distance from the skin to the upper and lower pole calyces and flattens the renal angle, improving access to the upper pole through a lower pole puncture.

a puncture 30° from the vertical [12]. A study using images from reconstructed magnetic resonance imaging (MRI) scans reaffirmed the preference for more medial puncture to avoid iatrogenic injury to the spleen and liver [42].

Several studies have utilized both CT and MRI to study these changes and estimate the relative risk of iatrogenic organ injury during renal puncture. The colon is most at risk from lower pole access [43–45]. One group found the incidence of retrorenal colon was 4.7% in the prone position and 1.9% in the supine position [44]. However, in a study of reformatted CT scans, Tuttle et al. demonstrated that axial CT scans may dramatically overestimate the risk of colon injury associated with lower pole puncture [43]. On axial CT reconstructions, compared to oblique and parasagittal CT, there was a 15.1 and 3% risk of colon injury in the prone position, respectively, with no risk to liver, spleen, or lung. These findings are more in keeping with clinical series demonstrating low rates of organ injury. In a large clinical series, of almost 1600 prone PCNLs, the rate of bowel injury was 0.06%, with no cases of splenic or liver injury [46]. Similarly, in another series of 5039 prone PCNLs, the colon injury rate was 0.3% [45]. Multivariate analysis determined that older age and presence of horseshoe kidney were independent risk factors for colon injury.

Organs at risk from upper pole puncture include the liver, spleen, and pleural space [42, 47, 48]. Risk of organ injury varies considerably amongst published reports. In one study, the predicted risk of injury to the liver or spleen with upper pole puncture between the 11th and 12th rib was approximately 15% in the supine position, but decreased to zero by changing body position from supine to prone [47]. However, prone access between the 10th and 11th rib increased the risk of liver or spleen injury to 14% on the right and 94% on the left. Fortunately, these complications are exceedingly rare. A systematic review of PCNLs reports published between 1985 and 2013, included only 11 splenic, one liver, and eight gallbladder injuries [49]. This study emphasises that early identification and management are crucial to prevent patient morbidity and mortality.

Falahatkar et al. state that the colon “floats away from the kidney when the patient was in the supine position” [19]. Our CT studies did demonstrate that the colon was more medially situated and theoretically more prone to injury in the prone and prone-flexed positions compared with the supine position; however, the overall effect was minimal. Anatomically the colon is attached laterally to the peritoneum of the side wall of the abdominal cavity at the level of the kidneys and movement is restricted. The more lateral approach of the supine position would therefore still be more likely to result in the rare complication of colonic injury, which has been reported in this position [38].

### Thoracic complications

The risk of pleural injury is of considerably greater concern where significant complications include pneumothorax, hydro/hemothorax, damage to lung, and empyema. The diaphragm inserts onto the 12th and 11th ribs with the pleural reflection running horizontally and crossing the midpoint of the 12th rib in the majority of patients. The risk of pleural injury is therefore related to the position of the kidney in the retroperitoneum, the level of the pleural reflection, and the calyx chosen for access, and the phase of respiration. The majority of pleural complications occur with upper pole access. Hopper and Yakes showed that the predicted risk of injury to the lung from an upper pole puncture dramatically decreases from inspiration to expiration (86 to 29%, respectively) [47]. The same study did not show a difference in risk to pleura; however, the findings emphasize the importance of inserting the trocar needle in the upper pole with expiration. Significant complications include pneumothorax, hydrothorax, hemothorax, and empyema. In a study by Munver et al., the incidence of thoracic complications was 23.1% above the 11th rib, but dropped to just 1.4% above the 12th rib. The overall complication rates ranged from 4.5% for subcostal access to 9.7% above the 12th rib, and 34.6% above the 11th rib [50]. We have previously demonstrated that prone-flexed positioning results in inferior displacement of the kidneys inferiorly within the retroperitoneum, an effect which could result in fewer thoracic complications [12]. In an update of our previous report including data from the last 318 consecutive patients in our unit to be treated in the prone-flexed position, of which 16 (5.4%) of the tracts were above the 11th rib, 120 (40.8%) were above the 12th rib, and 158 (53.7%) were infracostal, there were only four pleural complications requiring chest drain insertion, representing 2.6% of the supracostal cohort [15].

### Hemorrhage and transfusion rates

Bleeding during PCNL, as well as delayed postoperative bleeding, is another complication that deserves attention. To prevent bleeding, the most important aspect is the end-on puncture of a posterior calyx. Using 3D polyester resin endocasts, Sampaio et al. demonstrated that the risk of arterial injury was highest from infundibular puncture and that the calyceal fornix provided the safest route of access [51]. Normally, the upper pole of the kidney is more medially and posteriorly located than the lower pole. Consequently, an upper pole posterior calyceal puncture lateral to the paraspinal muscles will result in access being more in line with the axis of the kidney. This is more likely to result in puncture along the avascular line of Brödel and less torquing of the kidney to reach the lower calyces and, consequently, less chance of the parenchyma splitting and bleeding. An angled tract that is not in line with the infundibulum or renal axis, or a puncture of the lateral calyces, will require more torque to reach the stone, which may result in unnecessary bleeding and increased transfusion rates. Choice of the appropriate percutaneous tract through a posterior calyx in line with the infundibulum will allow the operator to achieve a transfusion rate for PCNL of approximately 1% [46]. In an update of our previous report reviewing data from 318 consecutive PCNLs at our center, including patients with staghorn calculi and multiple tracts, no patient required blood transfusion or angioembolization [15].

### Neurologic complications: cerebrovascular accident, spinal cord ischemia, and nerve injury

Cerebrovascular accident, coma, and paralysis during PCNL are rare with a combined incidence below 0.1% [52]. The majority of these cases have been contributed to paradoxical air embolism from the use of air to perform retrograde pyelogram [53, 54]. However, inadequate spinal cord perfusion is also suspected to be due to stretch in the prone position, having the face turned or face down, and hypotension [52]. As such, use of air for retrograde pyelograms should be minimized and perioperative care taken to avoid these potentially devastating complications.

Injury to spinal nerve roots as they exit the spinal column as a result of percutaneous access in the prone position is rare but there are published case reports of two patients with renal anomalies [55, 56]. These complications can have permanent and catastrophic consequences but, in patients with normal renal anatomy, can usually be prevented by using a puncture site lateral to the paraspinal muscles and avoiding medial angulation towards the spine.

## Complications specific to patient positioning

### Anesthetic considerations

Anesthetic concerns garner much attention in prone percutaneous surgery and have been the driver of much of the renewed interest in supine PCNL. Another concern has been the maintenance of prone anesthesia in obese patients or those with cardiovascular or respiratory compromise. Although we have found that the prone-flexed modification may further increase airway pressures in obese patients, necessitating a reduction in patient flexion, we have not found it necessary to revert to conventional prone positioning [57]. As with other authors, in the morbidly obese patient we favor lateral or lateral-flexed positioning as this avoids abdominal compression and allows the anesthesiologist free access to the patient's airway [2, 3]. Others have reported using the lateral decubitus position in high-risk patients under regional anesthesia [58], as well as awake endotracheal intubation with prone self-positioning [59] as ways to overcome these difficulties. In two large reviews of complications during prone PCNL, no complications were attributed to the physiologic changes associated with prone positioning [46, 48, 60].

The greatest risk of airway loss is when the patient is positioned prone. For this reason, secured endotracheal anesthesia is preferred [61]. However, even with a cuffed endotracheal tube problems may occur. Obstruction of the tube may occur due to kinking or secretions draining under gravity in this position [62]. Fortunately, such concerns remain largely theoretical and complications are limited to case reports.

In rare circumstances, insertion of central venous monitoring or cardiac compression and defibrillation is necessary in the prone patient. When possible, it is advisable to return the patient to the supine position and to have a stretcher standing outside the OR for this purpose. However, when there is need for a prolonged delay in repositioning due to instrumentation protruding from the flank, successful insertion of central venous line and cardiac resuscitative efforts with the patient positioned prone have been reported [63–65].

### Cardiovascular changes

The greatest body of research related to the effects of prone and prone-flexed patient positioning comes from spinal surgeries, where the impact of patient position on both physiology and surgical outcome has long been recognized. Hemodynamic changes related to patient positioning remain controversial and likely depend on the underlying cardiovascular status of the patient, the precise body position, and the use of saddles/bolsters. It is generally agreed that prone positioning causes a decrease in cardiac index. However, this is not felt to be clinically significant as mean arterial pressure in the prone and prone-flexed positions is maintained due to an increase in systemic vascular resistance [61, 66, 67]. In a study of 19 patients, Hatada et al. concluded that the drop in cardiac index presented no significant challenge to the maintenance of anesthesia [68]. Other groups have also reported this finding [66, 67]. In the prone and prone-flexed positions, mean arterial pressure appears to be maintained due to an increase in systemic vascular resistance [66].

Prone positioning may also lead to transient inferior vena cava obstruction. In spinal surgery, this has led to speculation that impeded venous drainage may contribute to increased bleeding during surgery [69]. Whether this may also play a role in blood loss during renal surgery remains unknown but our data would suggest that this is not a concern. It has been shown that relieving abdominal compression by placing a bolster under the patient's chest and padding of the anterior superior iliac crests can dramatically decrease the effect [70].

### Respiratory changes

As with cardiovascular changes, changes in pulmonary physiology vary considerably with patient position, body habitus, and the amount and type of padding/support used. Although tidal volumes and inspiratory flow rates are preserved in the ventilated patient, functional residual capacity consistently increases with a change from supine to prone position [61]. One study found that prone positioning did not significantly affect compliance and that respiratory resistance increased only slightly in nonobese patients [71]. As both functional residual capacity and $P_aO_2$ markedly increased from the supine to the prone position, the authors concluded that, during general anesthesia, prone positioning did not have a negative effect on respiratory mechanics, instead improving both lung volumes and oxygenation [71, 72]. Interestingly, these improvements were maintained in a similar study in anesthetized and paralyzed obese patients in the prone position [71]. Siev et al. also found that the peak inspiratory pressure does not increase significantly with prone positioning [73]. It has been hypothesized that improvements in gas exchange may be due to changes in pulmonary blood flow and redistribution of lung ventilation, resulting in better ventilation/perfusion matching [61]. Importantly, the requirement for free abdominal and chest-wall movement cannot be overemphasized in the surgical patient.

### Ophthalmic complications

Eye injuries resulting from surgery are extremely rare, with an incidence of approximately 0.1% following nonocular surgery [74]. Corneal abrasions account for the majority of these injuries, but rarely result in vision loss. In the prone position there is also a theoretical risk of blindness, due to increased intraocular pressure which can result in blindness due ischemic optic neuropathy or central retinal artery occlusion [60, 75]. Fortunately, this complication is rare and has mainly been reported during spinal surgery, especially with prolonged OR times in excess of 6 hours in the prone position [76, 77]. We are unaware of any cases following PCNL. For patients with one eye at increased risk of elevated pressure, rotating the head at 45° decreases the intraocular pressure measured after the procedure in the upper eye, compared to the more dependent eye [75].

### Peripheral nerve injury

Positioning-related peripheral nerve injuries occur secondary to stretch, ischemia, or compression. The combined factors of time, mechanical pressure, and immobility place patients at risk for these complications. Recovery can be variable and is directly related to the severity of the injury.

Special care must be taken with patients in the prone position as they are susceptible to brachial plexus injuries [78]. Such injuries are most commonly due to nerve stretch from extreme shoulder abduction; however, external compression can also play an important role. Prolonged surgical procedure has also been suggested as a contributing factor. Typically, these injuries present as painless motor dysfunction. To prevent this complication, some authors recommend tucking the arms at the patient's side during the procedure. We find that abduction of the shoulder to approximately no more than 90°, with elbow flexion, relieves undue stress. Ideally, the arm should be well padded and rest below the level of the patient's chest. Additionally, for patients in the prone and prone-flexed positions, the head must be maintained in a neutral position, to preventing lateral flexion. Fortunately, the prognosis for these injuries is usually good. In one study, following a cohort of 22 patients with brachial plexus injury, including 14 following noncardiac surgery, complete recovery was achieved in 79% [79].

Nerve compression injuries may also occur in other operative positions. In the lateral position, the ulnar nerve is at risk from the edge of the OR table. The majority of these injuries can thus be prevented by adequate padding at the elbow and supination of the dependent arm [80]. In particular, flexion of the elbow of greater than 90° is a known risk factor and is due to shrinkage of the cubital tunnel, resulting in compression of the ulnar nerve [81].

Injury to the peroneal nerve has commonly been described in association with the dorsal lithotomy position. Many surgeons use Bierhoff leg holders when placing patients in this position. Long duration of the procedure has been implicated in this type of injury [82]. General guidelines for use of these supports include: (i) slow and simultaneous placement of the legs into their final position and (ii) limiting the amount of hip flexion, abduction, and lateral rotation [78]. In the lateral decubitus position, compression of the unpadded fibular head against the OR table during nephrectomy resulted in peroneal nerve injury in one patient [83]. Sciatic nerve compression between the OR table and the ischial tuberosity has also been known to occur in patients in the semilateral position as well as in the lithotomy position [78, 82].

Fortunately, the great majority of intraoperative nerve injuries are preventable. A high level of suspicion is important when recognizing these injuries as patient complaints in the early postoperative period may be easily dismissed. Careful attention to patient positioning, the use of adequate padding, and awareness of patient comorbidities such as skeletal deformity are all essential components. When peripheral nerve injuries do occur, prompt referral to a neurologist who specializes in these types of injury is required.

## Prone versus supine PCNL

### Studies comparing supine and prone PCNL

Several randomized studies have compared prone versus supine positioning for PCNL [18, 19, 84–87]. DeSio et al. randomized 75 patients with stones treatable with single percutaneous access, stone(s) >2.5 cm, and BMI <30 kg/m$^2$ to prone or modified supine PCNL [18]. Falahatker et al. randomized 80 patients with stones treatable with single percutaneous access and stone(s) >2 cm to prone or complete supine PCNL [19]. More recently, Abdel-Mohsen et al. randomized 77 patients with BMI <40 kg/m$^2$ to prone or free-flank modified supine PCNL [84]. In a similar study, Wang et al. randomized 122 patients with renal (>2 cm) or ureteric (>1.5 cm) stones to prone or modified supine PCNL [87]. Karami et al. randomized 150 patients to prone or complete supine, both with fluoroscopically guided access, or lateral PCNL with ultrasound-guided access [85]. Al-Dessoukey et al. randomized 203 patients with stones renal stone(s) >2.5 cm or upper ureteric stones >1 cm or smaller stones with previously failed shock-wave lithotripsy to prone or oblique supine lithotomy PCNL [86]. Unfortunately, these studies have relatively small sample sizes and many have different results, therefore preventing definitive answers about the differences between prone and supine PCNL.

In addition, these studies compare different supine positioning techniques. Despite these differences, three studies have combined data on prone and supine PCNL and performed meta-analyses [59, 88, 89]. Liu et al. combined two randomized and two case controlled studies including a total of 389 patients [88]. Wu et al. combined four comparative studies and 27 case series, comparing 4837 prone and 1469 supine PCNLs [59]. Zhang et al. combined two RCTs and seven non-RCTs comparing 4956 prone and 1457 supine PCNLs [89]. Over a 2-year period, the registry-based prospective CROES collected nonrandomized data for the PCNL Global study and has produced many important findings. One subgroup analysis used this registry to compare PCNL in 4637 prone and 1138 supine procedures [90].

## Hemodynamic and ventilatory changes

Al-Dessoukey et al. showed that oblique supine lithotomy positioning PCNL compared to prone had less change in mean blood pressure (−2 vs. −14.06 mm, respectively), heart rate (−0.82 vs. +13.28 beats per minute, respectively), and peak airway pressure (+1.08 vs. +7.56 $cmH_2O$, respectively) [86]. However, the clinical relevance of these differences has not been studied.

## Access and failed PCNL

Due to the anatomic changes while supine, the number of potential access sites is decreased compared to prone PCNL. Yazici et al. found that the access field was shorter in supine compared to prone and prone-flex positions (80.8, 86.3, and 86.7 mm, respectively) [91]. As such, more limited field access in supine may result in more failed access. In the CROES PCNL Global study there were more failures in the supine PCNL group compared to the prone (2.4 vs. 1.5%, respectively) [90]. However, lower pole puncture in the supine position may offer greater accessibility to the upper pole calyces compared to prone [92].

## Stone-free rates

Stone-free rates are highly variable based on center and definition. An argument given by proponents of the supine technique has been that it is more ergonomic and facilitates stone clearance through spontaneous evacuation from the dependent nephrostomy tract. However, in the supine position stone fragments also collect in the dependent posterior calyces rather than the renal pelvis, as is the case when the patient is prone, allowing for easy removal.

Four RCTs and two meta-analyses failed to show a difference in stone-free rates between prone and supine positing [18, 19, 27, 84, 85, 88]. One RCT found that prone PCNL was associated with a greater stone-free rate compared to modified supine (89 vs. 73%, respectively) [87]. Similarly, the meta-analysis by Zhang et al. found that prone positioning was associated with a higher stone-free rate (odds ratio 1.36) [89].

The CROES PCNL Global study also found that prone PCNL was associated with a higher stone-free rate compared to supine (77% vs. 70%, respectively) [90]. However, the authors note the substantial difference between these rates and those previously reported in comparative studies. In a subset of 1311 patients in the CREOS registry with staghorn calculi, prone PCNL had a higher stone-free rate compared to supine (48.4 vs. 59.2%, respectively) which persisted after multivariate analysis adjusting for number of access sites and method of determining stone-free status [93].

## Intraabdominal organ injury

In an attempt to overcome some of the difficulties associated with prone positioning, there has been a resurgence of interest in PCNL performed with the patient supine. The first report on supine PCNL, by Valdivia Uria et al. in 1998, included 557 patients [10]. In this position, puncture is performed under fluoroscopic or ultrasound guidance either in or anterior to the posterior axillary line (see Chapter 10). This distinction is important as the resulting tract is significantly more lateral than the access used in prone or lateral PCNL. In their original report, Valdivia Uria et al. expressed a preference for puncture of anterior calyces, with low complication rates; however, transfusion rates were not reported. Other authors have similarly found that puncture of anterior calyces is often necessary in the supine position [15, 63]. As noted, rates of adjacent organ injury are rare when performing PCNL. As noted above, the colon floats away from the kidney with the patient in the supine position [19]. Our data from axial, triphasic CT scans performed with the patient prone, prone-flexed, and supine supported this statement. However, the overall effect was small and would likely be diminished by the more laterally placed tracts necessary with supine PCNL. Of 1720 supine procedures in the literature, reported in the literature to date, only one case of bowel injury has been reported (0.00058%) [94]. Anatomically the colon is attached laterally to the peritoneum of the sidewall of the abdominal cavity at the level of the kidneys and movement is restricted. The more lateral approach of the supine position would therefore still be more likely to result in the rare complication of colonic injury, which has been reported in this position [94].

In all of the randomized studies there was no difference in organ injury between prone and supine positioning [18, 19, 84–87]. In total there were two colon perforations in the prone position and two pleural effusions in the supine position [85, 86]. However, with 707 patients in total, given the rarity of these events, the power to detect a difference may be insufficient [18, 19, 84–87]. The CROES PCNL Global study found similar organ perforation rates in the supine (3.4%) and prone (3.3%) groups [90].

### Blood loss and transfusion rates

Bleeding following PCNL is another area that deserves attention. A review of all studies published to date demonstrated an overall transfusion rate of 4.6% (range 0–20%) with PCNL performed in the supine position [15, 16, 38, 63–72]. The higher transfusion rates may be partly due to renal shear, as puncture of an anterior or lateral calyx in the lower pole would result in more manipulation when using a rigid endoscope to access the full length of the collecting system. Additionally, end-on fluoroscopic views of the calyces in this position are obstructed by the patient's spine and side rails of the OR table, particularly in oblique views. As a result, the triangulation method of fluoroscopic puncture may be necessary or, more commonly, ultrasound-guided access. In the latter case, special expertise may be necessary to perform end-on calyceal puncture to avoid the intrarenal arterial injuries that can be the cause of profuse bleeding during PCNL [41].

Four studies have performed a direct comparison of prone and supine positioning during PCNL by the same surgeon [15, 16, 38, 63]. Due to small sample sizes, no significant difference in transfusion rate was noted by any group. There is mixed results regarding blood loss in supine versus prone PCNL. Randomized trials by De Sio et al. and Falahatker et al. did not find a difference in mean blood loss or transfusion rates [18, 19]. However, in another randomized trial Aldessoukey et al. found supine PCNL to have less mean hemoglobin loss compared to prone (−1.03 and −2.18 g/dl, respectively) [86]. The CROES PCNL Global study also found a higher blood transfusion rate in the prone position versus supine (6.1 vs. 4.3%) [90]. However, this study did not correct for differences in renal anomalies, number of percutaneous access sites, and American Society of Anesthesiologists (ASA) classification score, all of which could have contributed to the higher blood loss.

### Operative times

Despite repositioning, some studies suggest that prone PCNL may be associated with shorter operative times. Randomized studies by Abdel-Mohsen et al. and Wang et al. found that compared to supine the operative time for prone PCNL was 16 and 10 minutes shorter, respectively [84, 87]. The CROES PCNL Global study also found that prone PCNL is associated with a shorter operative time compared to supine in all patients (82.7 vs. 90.1 minutes, respectively) [90] and a subset of 1311 patients with staghorn calculi (103.2 vs. 123.1 minutes, respectively) [93]. However, the Liu et al. meta-analysis found prone PCNL to take longer than supine by 25 minutes [88].

### Obese patients

Despite concerns regarding hemodynamic stability and ventilation, prone PCNL may be the best option for most obese patients. A recent study found that although obese patients have higher peak inspiratory pressures in the supine and prone positions compared to non-obese, peak inspiratory pressures does not change from supine to prone positioning [73]. Furthermore, as supine positioning has an increased tract length compared to prone by as much as 2 cm, obesity further complicates the procedures in an already challenging subgroup of patients [91]. In a review, de la Rosette et al. examined the effect of patient positioning, concluding that for obese patients, or those with staghorn calculi, the prone position was associated with similar bleeding rates, but decreased operative times, and slightly improved stone-free rates compared to the supine position [38]. However, a review by Mazzucchi et al. of 42 obese patients undergoing PCNL found that prone positioning was associated with higher transfusion rate, as well as longer operative times and hospital stay compared to supine [95].

## Conclusions

Appreciation of the calyceal anatomy and the ability to choose the appropriate posterior calyx for percutaneous access in the prone position will allow the operator to perform the procedure with minimal morbidity. Prone-flexed positioning is a simple modification that is well tolerated by the patient and offers significant surgical advantages. The lateral position is well suited to the morbidly obese patient, while the lateral-flexed position adds further advantages and is familiar to all urologists. Treating urologists must be familiar with the potential complications of PCNL and ways to prevent and manage them. Compared to supine, prone positioning has similar complication rates but may increase chances of successful access and stone-free status and is likely better suited for obese patients and treating staghorn calculi.

## Percutaneous Nephrolithotomy Access Under Fluoroscopic Control

*Norberto O. Bernardo*[1] *& Maximiliano Lopez Silva*[2]

[1] *Hospital de Clínicas José de San Martín, Universidad de Buenos Aires, Buenos Aires, Argentina*
[2] *Clínica San Camilo, Buenos Aires, Argentina*

The last years of the 1970s and the early 1980s will probably be remembered by urologists as a time of tremendous changes, in particular the whole concept of minimally invasive surgery and the development of percutaneous surgery, which have shown spectacular clinical results and reduced the morbidity of open surgery [1]. Percutaneous stone extraction was first described more than 40 years ago and has become an increasingly common intervention for patients with stone disease [2, 3], evolving into a safe and effective treatment for patients with large or otherwise complex stone disease. However, despite the increasing use of percutaneous renal surgery, Lee et al. reported that only a minority of urologists (27% of those who have trained in percutaneous access) actually gain their own access for percutaneous nephrolithotomy (PCNL) [4]. One of the more common reasons given by respondents for not doing so was inadequate skills in the techniques of access.

The placement of percutaneous access into the intrarenal collecting system is one of the most critical aspects of percutaneous renal surgery. Image guidance is a critical factor for the performance of percutaneous minimally invasive procedures, which are being used with ever increasing frequency. Procedures such as PCNL are not performed without image guidance. The puncture of the kidney, insertion of guidewires, establishment of the percutaneous tract, and the disintegration and removal of stones are based on appropriate image guidance. For percutaneous renal surgery using fluoroscopy, access must be gained: different forms of access have been developed, all with the indispensable assistance of the image intensifier [5].

The first percutaneous nephrostomy to decompress an obstructed kidney was described by William Goodwin in 1955 [6]. However, removal of a renal calculus via a percutaneous tract established specifically for that purpose was not performed until 1976, when Fernstrom and Johansson used the technique successfully in three patients [7]. In their series, the tract was slowly dilated under fluoroscopic control over a 7-day period to a size sufficient for stone extraction. Similarly, Alken et al. in their experience with PCNL established access to the renal collecting system over the course of weeks, by repeatedly dilating it with hand-shaped polyethylene tubes of increasing size [8]. He subsequently developed metal telescope dilators to solve the problems met during the treatment of his first 21 patients, which accelerate the procedure and allow percutaneous stone removal to be performed in a single session with a delicate set of instruments. In 1982, Smith et al. described the rapid dilation of the nephrostomy tract in minutes with no untoward effects, which revolutionized the field of percutaneous stone surgery and contributed to the demise of open surgery [9]. Since that time the percutaneous approach has generated wide interest among the pioneers of endourology, and they developed and popularized most of the basic principles in this area in the late 1970s.

## Fluoroscopy

Imaging equipment in percutaneous renal surgery typically uses radiation for image formation and guidance during access and tract dilation.

Fluoroscopy is useful during the advancement of guidewires, tract dilation, stone removal, and nephrostomy placement, providing real-time depiction of the collecting system and the stones therein. Percutaneous renal surgery is performed with a combination of fluoroscopic

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

and endoscopic visualization of the collecting system. Fluoroscopy is a two-dimensional method and provides limited information regarding the surrounding soft tissue. Nevertheless, it has proven to be an invaluable tool for the performance of percutaneous procedures of the kidney and collecting system.

## Radiation exposure

All parameters of fluoroscopy affecting image quality, reproducibility, and radiation output from each radiographic unit must be evaluated routinely to ensure optimal image quality while minimizing the radiation dose [10]. The endourologist can improve their imaging techniques and minimize both their and the patient's radiation exposure with no concurrent loss of image quality.

When attempting to obtain a diagnostic-quality image and the image is underpenetrated, and given the choice between increasing the total number of X-rays (mA) or the penetrability of the X-rays already present (kVp) to improve the image, the kVp should be increased initially as this will not increase the radiation output [11]. Collimating the image to the minimum size necessary for performing the work will reduce the amount of unnecessary radiation to which the patient and anyone else in the room is exposed. The radiation output from the X-ray tube should have been evaluated within the past year by a radiologic physicist, who determines whether the unit's radiation output is within legal limits as well as optimal for each examination.

There have been various reports evaluating the typical radiation exposure from fluoroscopy during PCNL, with an estimated effective dose between 7.63 and 8.66 mSv. Certain risk factors increase radiation exposure during PCNL. These include high body mass index, increased stone burden, and increased number of access tracts [12]. In a prospective study of PCNL and obesity, total operative time and radiation exposure increased as patients' body mass index increased, in part due to technical challenges. Obesity increased fluoroscopy time by 36% and mean effective dose by 177% [13].

Radiation "spreads out" in a three-dimensional (3D) space with a discrete or fixed number of photons spreading out into successively larger spaces. As a result, the area increases geometrically as a function of distance from the source. Increasing the distance from the source is one of the least expensive and most dramatic ways to reduce the dose of radiation to which operating personnel are exposed. By doubling the distance from the source, the radiation is reduced to one-quarter of its original intensity because the same number of photons is in a space that is four times larger. Similarly, by tripling the distance, radiation is reduced to one-ninth. Moving 1 m further away from an initial distance will reduce the dose by 89%.

The principle of radiation exposure to be as low as reasonably achievable (ALARA) should be followed during procedures that require fluoroscopy. A drape placed over or under the patient helps reduce scatter radiation [12]. Shielding, whether provided by lead aprons or thyroid shields, is a method of last resort. It provides excellent protection and should always be worn by those who work near the fluoroscopy table to limit the dose of radiation to which they are exposed. When fluoroscopy is performed, the radiation dosimeter badge is worn on the collar, outside the apron. As a result of this technique, the actual effective whole-body exposure is up to 99% lower than the dose measured by the badge [14].

Component positioning on the C-arm can significantly influence scattered radiation fields. The image intensifier should be as close to the patient as possible and the image should be collimated as much as possible over the area of interest. When the image intensifier is placed above the patient, and the tube is shielded by the table, both leakage and scatter radiation are minimized. Foot control must be entrusted to the operator and not to a third party, allowing better coordination, and audible alarms with a fluoroscopy locking system are very useful.

The introduction of digital radiography has contributed to the reduction of radiation exposure as well as to the improvement of image quality [15]. The combination of digital radiography with image storage systems and use of image processing systems resulted in the prevention of unnecessary image duplication and facilitated preoperative planning. A new generation of equipment has been designed with patient and operator dose reductions central to its development. Pulsed fluoroscopy and digital imaging have become available that reduce the dose of radiation delivered to the patient. Pulsed fluoroscopy should be set at the lowest possible frames per second that provide an image quality adequate for performing PCNL. Digital equipment eliminates the need for film; the information is electronically captured and manipulated on computer. As a result, the image can be enhanced, providing a sophisticated tool for dynamically evaluating patient organ function using editing techniques.

Radiation exposure can be a deleterious problem in percutaneous surgery, especially for the surgeon [16, 17]. There are two types of generalizable effects from radiation exposure: deterministic and stochastic effects. Deterministic effects are dose-related; therefore, if you have received a high-enough dose equivalent, certain types of effects will appear. For example, if dose exceeds 2 Gy, skin erythema will be observed. Stochastic effects are characterized by the absence of a threshold dose. Increased levels of exposure do not affect the type or severity of the effect, but do increase the probability of an effect. Risk of malignancy from radiation exposure is a stochastic effect. Common malignancies include leukemia, multiple myeloma, and thyroid, bladder, breast, lung, ovarian, and colon cancers. The National Council on Radiation Protection and Measurements has recommended an annual occupational limit of 50 mSv [18]. In medicine, there are no suggested limits for patient exposure. Instead, the risks from radiation must be balanced with the clinical necessity and benefit of the imaging study or procedure [12]. The use of ultrasonography can eliminate the side effects of radiation exposure during fluoroscopy-guided PCNL, and it can be used as a reliable method for localization of renal stones, especially nonopaque stones that are not visible with fluoroscopy. Also B-scan sonography can be used as a tool for localization of intrarenal arteries and avoidance of puncture by a Chiba needle.

### Ultrasound versus fluoroscopy-guided access

The advantages of ultrasound- over fluoroscopy-guided access into the collecting system include reduction of exposure to radiation for the urologist and operating room personnel (see also Chapter 16 in this volume). In pregnancy and in patients with transplanted, horseshoe, or ectopic kidneys, ultrasound represents the modality of choice [19, 20]. Another advantage is proper localization of the adjacent organs for prevention of injury. The main disadvantage of this modality is the difficulty and the need for greater care when the collecting system is only mildly dilated.

Ultrasound has been used by several groups for the guidance of PCNL, especially during the puncture of the collecting system [21].The performance of puncture with ultrasound guidance and without use of fluoroscopy has also been reported [22]. While ultrasound can be a useful complement to access the kidney, it should be emphasized that fluoroscopy is an indispensable component of safe percutaneous surgery.

## Preoperative images

Conventional computed tomography (CT) has been used for diagnosis of urologic diseases for many years. Recently, unenhanced helical CT has become a serious alternative to intravenous urography [23]. For preoperative planning, helical CT depicts the extent, orientation, and location of renal calculi, which are useful for access selection in percutaneous procedures. In addition, the anatomic relationships of the collecting system with surrounding organs are delineated, and the performance of a safe puncture is possible [24]. Nevertheless, the inability to provide real-time imaging capability has prevented wider application of CT in interventional procedures [25].

The 3D reconstruction of CT images for planning of percutaneous procedures has been reported to be feasible and accurate. With the use of 3D rendering software, the anatomic relationships of the collecting system are provided, and access selection is facilitated. The usefulness of 3D-reconstructed CT images, however, is not widely accepted [26]. 3D CT-rendered images that combine axial CT, CT urography, and angiography have been used for preoperative planning of urologic procedures, such as nephron-sparing surgery. Renal lesions and vessels can be accurately detected [27, 28]. Recent improvements in CT technology provide rapid and continuous reconstruction of CT raw data and provide real-time CT imaging (CT fluoroscopy) [29, 30].

Systems as Uro Dyna-CT (Siemens Healthcare Solutions, Erlangen, Germany) installed in the endourologic operating suite provides not only standard X-ray and fluoroscopy but also interventional 3D imaging and cross-sectional image reconstructions. It also offers a 3D planning and laser-guiding puncture tool called the syngo iGuide. It may be an additional instrument that allows the urologist to handle complex punctures [31].

Magnetic resonance imaging (MRI) provides better depiction of the soft tissue in comparison with fluoroscopy and CT, but remains unreliable for the identification of stones in the collecting system or ureter. MRI can be obtained without exposure to ionizing radiation. Thus, the technique may be considered as an alternative to ultrasound in selected cases such as the pregnant patient. Nevertheless, the strong magnetic field used interferes with ferromagnetic foreign bodies or electronic medical devices that are frequently carried by patients, although improvements in electronic medical devices have minimized this problem [32]. Newly introduced multisensor detector and faster image processing systems, as well as more advanced MRI scanners, have rendered real-time imaging a reality (MR fluoroscopy). The latter technique has been used in interventional cardiology [33]. Percutaneous nephrostomy placement has been performed with the use of open configuration MRI. MR urography represents an evolving imaging modality that allows optimal noninvasive evaluation of many abnormalities of the urinary tract. The application of several technical modifications provides adequate information for preoperative planning and postoperative assessment [34].

Each of these new technologies offers several potential advantages over the traditional percutaneous approach under fluoroscopic control. It should, however, be stated that all of these technologies are in a nascent stage of development. For that reason it is necessary to reinforce the basic concepts governing the realization of a conventional procedural approach to the kidney under fluoroscopic control. While this conventional approach is appealing, only a small percentage of urologists are

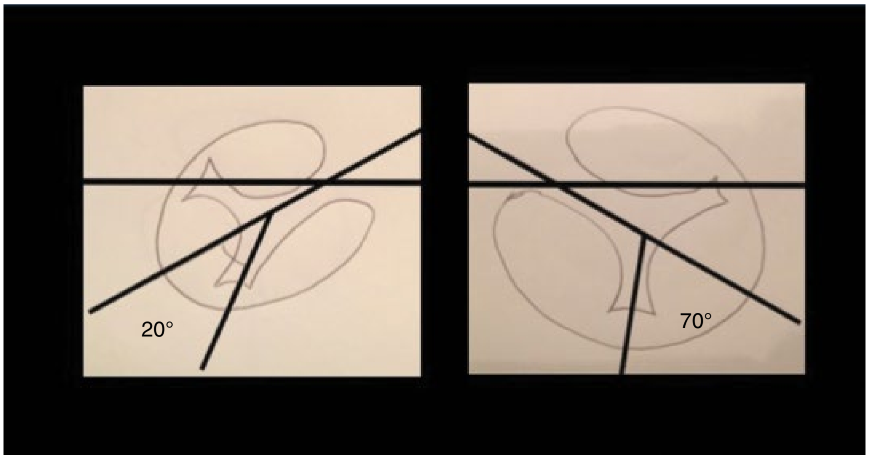

**Figure 13.1** Schematic view of both kidneys. Right kidney: posterior calyces positioned 20° posteriorly to the its own frontal plane. Left kidney: posterior calyces positioned 70° posterior to its frontal plane.

familiar with it [4], and various training models are essential for consolidating the use of this surgery [35, 36].

## Percutaneous renal access under fluoroscopic control

The information provided by preoperative helical CT is very valuable at the time of puncture under fluoroscopic control [37], as it identifies the most suitable place to set the path of the needle from the skin to inside the calyx that has been chosen for tapping. A CT scan can assess the presence of adjacent organs brought into the path of the needle. In this case, there is the option to change that path at the time of puncture under fluoroscopic control or to decide that percutaneous access is contraindicated.

When deciding where to make the puncture, areas of parenchyma should be considered that are thick enough to maintain a stable needle path and prevent subsequent development of a fistula. Also, it is desirable to identify those calyces for which surrounding thickness of parenchyma will promote their spontaneous closure of the puncture. Areas of kidney with an extremely thin parenchyma should be avoided.

Also, the information provided by helical CT will allow paths to be planned that avoid simple cysts, which sometimes are present in the renal parenchyma and are frequently not picked up on fluoroscopy.

The collecting system is opacified with direct injection through the ureteral catheter of contrast. A posterolateral transparenchymal puncture minimizes the chance of injury to the major renal vessels. The chosen posterior calyx is visualized with the C-arm fluoroscopy unit in the posteroanterior direction initially. The posterior calyces are positioned 20° posteriorly to the frontal plane of the kidney in most right kidneys, and 70° posterior to the frontal plane of the kidney in most left kidneys. In a normally rotated kidney, the frontal plane of the kidney is 30° posterior to the coronal plane of the body (Figure 13.1). In general, all patients undergoing any percutaneous renal procedure are given a general anesthetic.

### PCNL in prone position

The patient is placed in a lithotomy position for cystoscopy, with insertion of a 6 Fr open-end ureteral catheter under fluoroscopy guidance. A retrograde urogram then delineates the ureteral anatomy, as well as the exact stone location, degree of hydronephrosis, and the image of the selected calyx in order to plan the approach to the collecting system if this is deemed necessary [38].

The rigid cystoscope is used to place a 0.038 inch Teflon-coated guidewire into the upper collecting system. When a tortuous area blocks the progress of the guidewire, a wire with a hydrophilic coating must be used. This wire is composed of an alloy core, a polyurethane jacket, and a thin hydrophilic polymer as the outermost layer. When in contact with fluid, the polymer binds water to create a lubricious coating with greatly diminished friction, avoiding excessive edema and creation of a false passage. When the guidewire is in position, the 6 Fr catheter is advanced over it to the renal pelvis, and the endoscope is removed.

A 16 Fr Foley catheter is inserted and attached to a drainage bag at the same time. Both catheters are tied with 2-0 silk to secure them in place. It is helpful to connect an empty syringe to the Luer Lock adapter at the end of the ureteral catheter to prevent urine leakage.

The patient is positioned prone to allow posterior access. The patient is moved slowly and gently to allow the body to adjust to the position change. A foam rubber pillow is placed under the head to prevent it from being angulated excessively in relation to the trunk. The endotracheal tube is placed in the side slot of the foam pillow, making sure that the tube is unobstructed and free from kinks. To reduce resistance to breathing, the chest and abdomen are elevated on two foam rubber rolls that extend from the shoulder to the hip. Knee donuts padded with sheepskin inside the ring are positioned between the knees and the operating table to protect the bony prominences. A foam rubber roll is placed anterior to the ankles. The arms are flexed and secured on padded arm boards, and the elbows are protected with sheepskin pads. At this time, the 2-0 silk tie securing the two catheters together is cut and discarded. The intravenous extension tubing is connected to a 60 ml syringe containing 25% diatrizoate (Hypaque) solution, and the tubing is primed. The nurse removes the empty syringe from the ureteral catheter and attaches the syringe and tubing to the Luer Lock adapter of the ureteral catheter.

The percutaneous access is created via an upper, middle, or lower calyx. Thorough evaluation of the renal collecting system anatomy is essential prior to definitive percutaneous puncture for access tract creation.

Percutaneous access to the upper urinary tract through a calyx must meet five conditions that guarantee safe access and avoid complications:

1) performed from a posterolateral position
2) performed through the renal parenchyma
3) toward the center of the calyx posterolaterally
4) toward the center of the renal pelvis
5) as a result of these four conditions, the trajectory does not damage any major blood vessels.

There are two primary methods used to gain fluoroscopy-guided percutaneous renal access: the bullseye technique and triangulation [39, 40]. Both techniques need a target, most commonly generated by opacification of the collecting system with iodinated contrast that is administered retrograde via a ureteral catheter. A calyceal entry point is selected to avoid the larger vascular structures that are found at the level of the infundibulum.

As with most percutaneous access techniques, the bullseye technique requires fluoroscopy to monitor and guide the procedure. To this end a ureteral catheter is placed and the patient is positioned as described above. With the C-arm in the 30° position, an 18G diamond tip access needle is positioned, so that the targeted calyx, needle tip, and needle hub are in line with the image intensifier, giving a bullseye effect on the monitor. In effect the surgeon is looking down the needle into the targeted calyx. The needle is advanced in 1–2 cm increments using a hemostat to minimize radiation exposure to the surgeon. Continuous fluoroscopic monitoring is performed to ensure that the needle maintains its proper trajectory. Needle depth is ascertained by rotating the C-arm to a vertical orientation. If the needle is aligned with the calyx in this view, the urologist should be able to aspirate urine from the collecting system, confirming proper positioning.

The triangulation technique is based on simple geometric principles and is guided by biplanar fluoroscopy; one plane is anteroposterior to the line of puncture and the other is oblique. The anteroposterior view may be considered to be in a plane parallel to the axis of puncture and is used to monitor mediolateral (left–right) adjustments. The oblique view gives information regarding depth to the site of puncture and is used to monitor needle adjustments in the cephalad–caudad (up–down) orientation.

The tip of the needle is oriented towards the calyx to be punctured in both the anteroposterior and oblique planes. Left–right adjustments are limited to the anteroposterior view only, and cephalad–caudad adjustments are limited to the oblique view. When making adjustments in the mediolateral axis, care should be taken not to inadvertently move the needle in the cephalad–caudad axis, and vice versa. In most cases, it is helpful for the surgeon to rest their arm on the patient during the access part of the procedure, as this minimizes unintended drifting of the needle away from the targeted axis and also provides additional needle stabilization.

To decrease the radiation exposure to the surgeon's hands, the C-arm should be oriented with the image intensifier angled toward the head of the patient. Whenever possible, the iris of the fluoroscope should be kept as small as possible, to further minimize stray radiation exposure. Once the needle is aligned with the targeted calyx in both the mediolateral and cephalad–caudad orientations, it is advanced with continuous fluoroscopy. The needle should always be advanced in the oblique view, which will allow for the assessment of the depth of the needle's penetration. It is helpful for the anesthesiologist to hold the patient's respirations while the needle is being advanced, to avoid having to "hit a moving target," as well as to minimize the risk of an inadvertent transthoracic puncture. After advancing the needle several centimeters in the oblique view, the anteroposterior view should be examined to confirm that the mediolateral trajectory of the needle is still properly aligned to the target. If necessary, the needle trajectory can be readjusted to maintain proper targeting. Again, it is critical not to alter the access needle's orientation in one plane while making adjustments in the other plane, particularly when advancing the needle.

Several groups have reported refinements in techniques, incorporating elements of the bullseye and triangulation methods, proposing new approaches, describing adjuncts, and using new technology. Mues et al. described a geometric model to create a plane of coincidence between the C-arm and the needle, each at the same angle of 20–30° from the targeted calyx, but in opposite directions [41].

For lower pole access, the C-arm is rotated cranially 30° from the vertical plane, and a needle is advanced from a position distal to the calyx, rotated caudally 30° from the vertical plane. For mid-renal and upper pole calyceal access, the C-arm is rotated 20° away from the surgeon, and a needle is advanced from a position lateral to the calyx, at an angle of 20° toward the surgeon from the vertical plane. In either case, the C-arm remains fixed, and the needle is advanced until the point of coincidence between the calyx and the needle tip is reached. This technique purportedly eliminates the need for C-arm rotation, thus potentially reducing C-arm manipulation and fluoroscopic exposure time. This technique, however, requires a plumb, protractor, and ruler to calculate and confirm the necessary measurements.

Another proposed modification by Sharma and Sharma represents a hybrid of the bullseye and triangulation techniques [42]. The posterior calyx that provides the best access for stone clearance is selected. The initial puncture needle is held at this point. The needle with its overlying hub in the same line as the calyx creates a bullseye effect on the C-arm monitor. The site on the skin corresponding to the target calyx is thus determined, and its position is marked with a hemostat as point A (see Video 13.1). We place an intramuscular needle at this point instead of a hemostat. Then, under direct vision, the needle is placed vertically and the puncture is made at this point in the subcutaneous cellular tissue at a depth of about 1 cm (Figure 13.2a). The visual control of the needle in the vertical position reduces fluoroscopic exposure to a few seconds. Subsequently, a brief fluoroscopic exposure is used to check the position of the needle and it is shown on the screen as a point. The trajectory of the line of puncture of the needle into the dorsal area represents an imaginary line through the selected calyx in the anteroposterior direction. However, this trajectory does not meet all five requirements for optimum puncture, described above, as the needle is not directed toward the center of the renal pelvis.

The C-arm is then angled toward the surgeon, 30° from the vertical in the axial plane. With the ventilation suspended in end expiration, the second puncture needle is held over the targeted calyx in such a way that the needle with its hub is in the same line with the calyx, which leads to a bullseye effect on the C-arm. This particular point on the skin is punctured with an intramuscular needle and is taken as point B (Figure 13.2b) (see Video 13.2). This position represents an imaginary line that is projected onto the center of the selected calyx. Again, all five requirements for safe renal puncture are not met because the trajectory is not toward the center of the renal pelvis. This position is checked in relation to the 12th rib. Visually observing the trajectory of the two small needles placed in the lumbar area, the intersection of two lines coincides with the desired calyx.

The distance between the two needles is measured (Figure 13.3a). The C-arm is then brought back to its vertical position. Now the line of puncture is determined in alignment with the infundibulum from point A. Along this point line, the point B1 is marked. The distance between points A and B1 is equal to or greater than the distance between the intramuscular needles (points A and B) (Figure 13.3b). The point B1 is the point where the skin is punctured for renal access. A small incision is then made at point B1 and the 18G needle is introduced for 1–1.5 cm (Figure 13.4). Now, with the C-arm in the 90° vertical position (i.e. parallel to the line of puncture), the mediolateral (right to left) adjustments are made. Then the C-arm is tilted toward the head of the patient by 30° and adjustments are made in the cephalad and caudal orientation of the line of puncture. The needle orientation is maintained in one plane while making adjustments in the other plane. With the C-arm in the oblique orientation, the needle is advanced with ventilation suspended in full expiration. Under fluoroscopic control and from this position, the 18G needle is advanced towards the point of intersection of the two lines that project both intramuscular needles to reach the selected calyx (see Video 13.3). This is the ideal path and the only one that meets the five requirements described above of a safe percutaneous renal puncture.

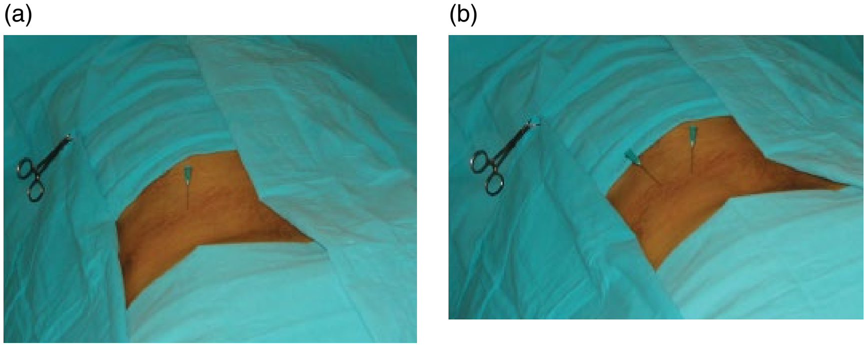

**Figure 13.2** (a) The intramuscular needle with its overlying hub in the same line as the calyx creates a bullseye effect on the C-arm monitor. The needle is placed upright and puncture is done at this point at a depth of about 1 cm in the subcutaneous cellular tissue. (b) The C-arm is angled 30° toward the surgeon. The second needle is held over the targeted calyx in such a way that the needle with its hub is in the same line with the calyx, which leads to a bullseye effect on the C-arm.

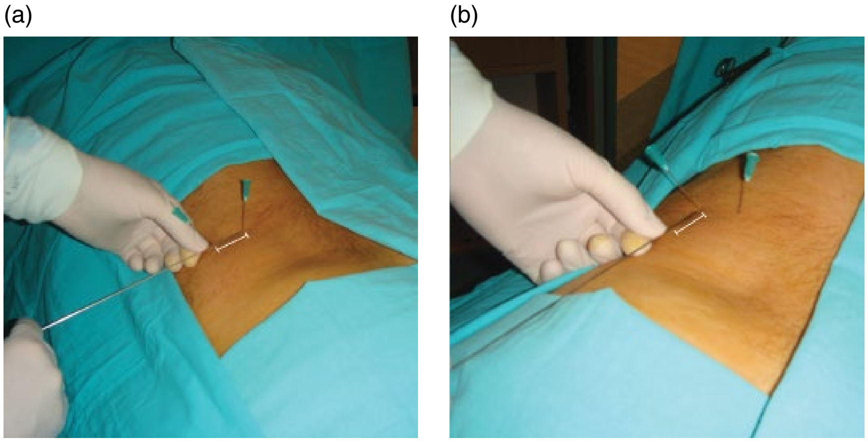

**Figure 13.3** (a) Distance between the two needles is measured (points A and B). (b) B1 is the point where the skin will be punctured for renal access. The distance between points A and B1 is equal to or greater than the distance between the intramuscular needles.

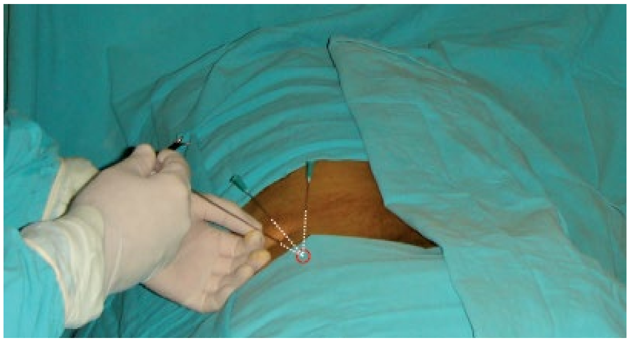

**Figure 13.4** The intersection of the two lines of small needles placed in the lumbar area coincides with the desired calyx. The 18G needle is advanced under fluoroscopic control towards the point of intersection of the lines that project from both intramuscular needles in order to reach the selected calyx.

When the tip of the needle appears fluoroscopically to be within the collecting system, the needle trocar is removed, leaving only the needle cannula in place, and a small amount of urine is aspirated to confirm the needle's intraluminal position.

Definitive puncture of the renal collecting system with an 18G diamond needle permits the immediate introduction of a 0.038 inch guidewire into the collecting system. The rigidity of this needle is advantageous for accurately directing the needle diamond tip as it is advanced through the fascial planes.

If at the point of withdrawing the trocar of the needle a spontaneous output of urine has not been observed, it is advisable gently to try to introduce a hydrophilic guidewire, observing the advancement of the guidewire under fluoroscopy. Typically, it moves into the cavity of the calyx and progresses towards the renal pelvis. If for some reason the guidewire does not easily advance, it is advisable to inject an additional volume of contrast through the initially placed ureteral catheter with the intention of filling the calyx cavity and thereby facilitating the progression of the hydrophilic guidewire.

If no urine exits from the 18G needle, it is not advisable to inject contrast through the needle, since contrast can extravasate, creating a lake of radio-opaque material and making it difficult to visualize the shape of the kidney cavities. Should this occur, the procedure must either be abandoned and returned to at another time, or the urologist must wait until there has been adequate absorption of the contrast material (see Video 13.4).

Several reports have been published of percutaneous renal surgery in the supine, modified supine, or lateral position [43, 44]. This has potential advantages over the prone position for PCNL but it has not been adopted by most urologists (see Chapters 11 and 12). The modified supine position preserves cardiovascular and ventilatory dynamics and allows better access to the respiratory tract. Additionally, the bowel slips away from the puncture area, lowering the risk of it being damaged. PCNL with the patient in a modified supine position may be considered for most patients, especially if concomitant ureteroscopy is planned [45].

## PCNL in supine position

With this technique it is possible to puncture the calyceal papilla without having to rotate the C-arm fluoroscope. Fluoroscopic control is maintained perpendicular to the needle and renal access. Initially a long metal instrument, as the nephroscope, is overlaid on the patient's abdomen and under fluoroscopic control its distal tip is placed over the selected calyx. This point is marked on the sterile drape as it indicates the orientation of the needle.

After having crossed the skin and muscular layers with the needle in an ascending direction to the selected calyx, if depth orientation is wrong it is necessary to retract the needle from the kidney and try to palpate it again in a higher or lower direction. When the selected calyx has been reached and the first urine drops are obtained through the needle, the guidewire is introduced and the tract can be dilated [46, 47].

### PCNL in lateral position

When PCNL is performed in lateral position it is important to consider the different degree of rotation presented by the posterior chalices of each kidney, as previously mentioned. In most right kidneys, the posterior calyces are positioned 20° posteriorly to the frontal plane of the kidney, and in most left kidneys they are 70° posterior to the frontal plane of the kidney (Figure 13.1). This shows that in left stones the needle will be inserted in a direction almost parallel to the operating table, whereas in right stones the needle will be inserted in downward position.

The triangulation technique is used, determining the cephalad–caudal axis with the C-arm in anteroposterior configuration, and determining the anteroposterior axis with the C-arm in oblique configurations [48]. Once the calyx is reached, the wire is introduced and we can proceed to dilation.

## Challenging situations

In situations where the volume of the stone occupies the entire volume of the calyx selected to be punctured, the needle is advanced until there is the tactile sensation of the needle tip touching the hard surface of the stone. In this situation the tip of the trocar of the needle is in contact with the stone but the cannula of the needle is at a distance of 1–2 mm from the surface of the stone. It is advisable to then move the cannula on the trocar toward the stone until contact with the surface of the stone is felt. Then the trocar needle is removed and the hydrophilic guidewire is gently inserted into the narrow space between the urothelium of the calyx and the surface of the stone. Sometimes this allows the advancement of the guidewire to the renal pelvis, but in other situations it is only possible to locate the guidewire in the punctured calyx and attempting otherwise is risky because of the short length of the guidewire in the upper urinary tract. The guidewire is advanced carefully across the calyceal infundibulum.

## Dilation

To perform tract dilation, a 1 cm skin incision is made around the needle with a no. 10 blade and the needle is removed. Then, in order to enlarge the defect in the lumbar fascia, a fascial incision needle can be used (no. 090070, Cook Urological). This instrument consists of an 18G needle fixed to a small, blunt, diamond-shaped blade that is passed over the puncture wire under fluoroscopic control and through the abdominal wall until it crosses the lumbar fascia (Figure 13.5). It is then withdrawn while gentle traction is placed on the puncture wire, and the tip of the blade is rotated 90° and then advanced again over the puncture wire in order to open the lumbar fascia more extensively. This action will facilitate the introduction of any of the available dilation systems.

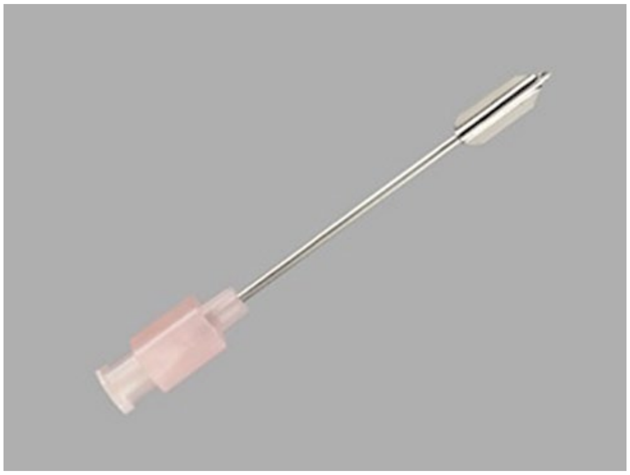

**Figure 13.5** Fascial incising needle. This instrument facilitates the introduction of any of the available dilation systems. It is used to open the lumbar fascia.

Acute dilation of nephrostomy tracts can be performed with a variety of instruments. These instruments are inserted over a working guidewire. Because of the risk of the perinephric guidewire kinking with loss of the nephrostomy tract and laceration of the renal parenchyma, all percutaneous dilator systems require fluoroscopic guidance [49–51].

The nephrostomy tract is dilated up to 30 Fr, according to the nephroscope to be used. In the serial dilation system, an 8 Fr Teflon catheter is used as an obturator. Progressively larger dilators are then serially inserted over this guidewire and catheter combination. This additional obturator stiffness greatly reduces the risk of perinephric guidewire buckling.

With the access tract dilated, a working sheath is introduced into the collecting system under fluoroscopic guidance over the 30 Fr (or the chosen diameter) dilator, which is then removed. The renal pelvis is examined nephroscopically to identify the obstructed segment of the ureteropelvic junction and locate the previously placed ureteral catheter. If necessary, either the ultrasonic probe or the grasping forceps are passed into the renal pelvis to clean out clots.

The catheter is grasped and brought out through the nephrostomy tract. A 0.038 inch super-stiff wire, which is a fixed core guidewire with an extra-stiff shaft and a flexible tip, is advanced through the catheter. A surgical assistant removes the ureteral catheter, leaving the guidewire in place at the urethral meatus. Once the ureteropelvic junction has been bridged (i.e. the guidewire is in position from the flank through to the urethral meatus), the nephroscope is removed and a hemostatic clamp is placed about 5 cm proximal to the distal end of the guidewire. It is pulled through the nephrostomy tract to position the clamp near the urethral meatus. This maneuver ensures the preservation of the nephrostomy tract, so that if the access route to the kidney is accidently lost it is easily recovered by following the guidance described above. Additionally, if for some reason the procedure has to be interrupted, placement of the nephroureteral stent will allow both drainage and subsequent easy access.

### Special situations: multiple access

In the treatment of complex renal lithiasis with branches in multiple calyces, it is sometimes necessary to make multiple punctures through different calyces. The multiple punctures can all be made initially, or alternatively one puncture can be made, through which most of the stone is removed and, if necessary, additional punctures can then be made.

If the planned multiple punctures are made at the beginning of surgery, the injection of contrast through the initially placed ureteral catheter facilitates visualization of all calyces and those most suitable for punctures can be chosen in accordance with the silhouette of the stone. The injection of contrast distends the upper urinary tract and this facilitates insertion of the needles into the calyces.

In contrast, if multiple punctures are made in addition to establishing a unique initial nephrostomy tract, the calyceal distention of the cavities may be hampered by the leaking of contrast that is injected by a 6 Fr ureteral catheter through the Amplatz sheath tract nephrostomy. In this situation it is advisable to place a Foley catheter and to inflate the balloon inside the Amplatz sheath to occlude its caliber. Thereafter it is possible to inject contrast either through the ureteral catheter placed at the beginning of surgery or the Foley catheter, and to place a clamp to prevent leakage of contrast from the distended renal cavity. This maintains the distention of the calyces, facilitating additional punctures under fluoroscopic control.

Liatsikos et al. have described the technique of a single subcostal skin incision with multiple angular punctures to approach the superior, middle, and lower pole of the kidney for the management of staghorn calculi [52]. Singla et al. have evaluated the safety and efficacy of an aggressive approach to staghorn calculi using multiple-tract PCNL, and reported a greater stone clearance rate without increasing the risk of significant complications [53].

## Conclusion

Percutaneous endourologic procedures require an advanced level of skill. The techniques used should be understood by those treating patients with complex renal stone disease to improve their ability to manage these often challenging clinical problems. The bullseye and triangulation methods are the most commonly used approaches, but refinements in technique and applications of new technology offer the potential for improved access with reduced patient and surgeon morbidity. Percutaneous puncture, tract dilation, and antegrade nephrostomy sheath placement into the desired calyx can be achieved rapidly and with precision when fluoroscopy is adequately used. For this reason and for patient comfort, access is best achieved in the operating room by the urologist, even in special situations like staghorn stones requiring multiple or supracostal accesses, calyceal diverticulum, and horseshoe kidneys.

## 14

# Dyna-CT-Guided versus Standard CT-Guided Renal Access

*Manuel Ritter & Maurice-Stephan Michel*

*Department of Urology, University Medical Centre Mannheim, Heidelberg University, Heidelberg, Germany*

## Background

The standard techniques for gaining access to the renal pelvis for percutaneous stone treatment are usually based on ultrasound and fluoroscopy. The exact technique depends on the imaging modalities that are available in different countries and medical centers. Both techniques have some drawbacks, especially in complex cases. Although ultrasound is a perfect real-time imaging tool, image resolution and contrast are limited, even in modern systems. Fluoroscopy provides a detailed depiction of the renal calyceal system using a contrast agent, but it does not offer the possibility of soft tissue imaging. Consequently, the risk of organ injury during the puncture or bleeding might be increased [1, 2]. Furthermore the two-dimensional (2D) depiction of the renal calyceal system obviously harbours difficulties for surgeons to visualize the anatomical three-dimensional (3D) situation during the puncture. The combination of both 2D techniques, ultrasound and fluoroscopy, might overcome this problem up to a certain degree, but 3D imaging has been proved to facilitate the procedure [3].

In the case of unsuccessful punctures of the renal calyceal system by standard techniques, computed tomography (CT)-guided access offers the possibility of depicting the kidney's surrounding structures and organs and with a high spatial resolution and therefore allows for gaining access even in special anatomical situations such as horseshoe kidneys, malrotation, or obese patients [4–6].

However, the procedure itself is more time consuming, expensive, and may cause higher radiation exposure to the surgeon and especially the patient. Due to these drawbacks CT-guided punctures of the kidney should be *restricted to special indications*. However, in cases of difficult anatomy, unclear ultrasound findings, or unsuccessful fluoroscopy-guided attempts, CT-guided punctures may be necessary [7]. The technique was first described in 1977 [8] and further developed over subsequent decades [9, 10]. The indications for CT examination of patients that undergo percutaneous nephrolithotomy (PCNL) might be puncture planning, puncture guidance, and control of puncture success [10]. Furthermore, CT scans after PCNL allow for fast and exact diagnostics of complications and provide the highest sensitivity for the detection of residual fragments. Routine application of post-PCNL CT provides additional advantages compared with other imaging modalities: namely, the identification of the presence and location of even small residual fragments, which has been shown to cause significant trouble and necessitate secondary procedures in a significant cohort of patients after PCNL [11]. As limited access to the patient inside the CT gantry and the need for several scans during a puncture are somehow limitations of punctures guided in multidetector-computed tomography (MDCT), cone-beam CT systems are now beginning to be used for gaining renal access not only by radiologists but also by urologists themselves [12]. Both techniques – standard CT-guided access and the 3D-planned, laser-guided access with a Uro Dyna-CT – are presented in this chapter.

## CT-guided access

### Patient positioning

For standard CT-guided access of the kidney, the patient is required to be in the prone position. For patients with respiratory difficulties a supine oblique position is possible but offers less working space for the interventional radiologist. The insertion point of the needle is marked

by a laser point (Figure 14.1). Angulation of the needle usually is not marked, unlike a cone-beam system. Therefore recurrent scans of the puncture area are necessary to check the needle direction during the puncture. Although the latest generation of CT scanners allows these recurrent scans with a relatively low radiation exposure it still leads to higher exposures than any other puncture technique. If the CT scan is used preoperatively for planning the puncture with a different technique, the patient should be placed in the same position that is used during surgery. CT scans that are performed in supine position do not provide sufficient anatomical information if the PCNL is to be performed in prone position.

## Puncture planning

The advantages of CT scanning over intravenous urography is the ability to assess the spatial relationship of the kidney relative to the stone, depict the calyceal anatomy in 3D format to choose the access site, assess the risk of pleural or bowel injury, and even predict success of subcostal fluoroscopic access for upper pole puncture [13, 14]. The preoperative detection of heptaosplenomegaly or the presence of retrorenal colon allows serious complications related to tract placement to be avoided [15]. Recent findings suggest that the preoperative use of CT angiography may reduce the risk of bleeding during PCNL. Patients who underwent CT angiography prior to PCNL had lower drop of hemoglobin and needed fewer transfusions [16]. However, similar results can be achieved with ultrasound-guided puncture techniques without any radiation exposure [17]. In patients with anatomical deformities, ectopic or transplant kidney, or suspicious ultrasound findings preoperative CT evaluation reduces the risk of intraoperative injuries and complications. Vasculature, retrorenal, or overlying bowel as well as pleural position in inspration and expiration are well indicated. In case access to the upper pole of the kidney is required as a result of stone position, CT examination helps to predict the success of subcostal and supracostal approaches [18]. Preoperative CT imaging enables the surgeon to measure the skin-to-stone distance and the ideal puncture tract. Especially in obese patients, knowledge of the expected tract length helps with choosing the right instruments (overlength) and avoids costly preparation of unnecessary devices.

## Radiation exposure

Radiation exposure is seldom reported in the published studies on CT-guided percutaneous renal access or nephrostomy placement. Published data are within a wide range due to different generation of CT systems and puncture techniques with and without CT fluoroscopy. The use of CT fluoroscopy increases the radiation exposure of the radiologist compared to the standard technique when the radiologist is outside the intervention suite during repeated scans and advances the needle between scans. Furthermore, modern generations of CT systems allow for fast evaluation of the area of interest during the procedures with relatively low radiation doses. Procedure time ranges from 7 to 50 minutes, with the dose area product being between 43 and 56 $\text{Gy/cm}^2$ and the effective dose 6.9–13.6 mSv [9, 19, 20]. The authors conclude that the procedure is not only time consuming but exposes the patient to significant radiation, too. Thus, the intervention requires a strict indication and should be performed exclusively when routine approaches have failed and preferably in older or oncology patients [19]. Another group evaluated the clinical impact of the use of a dose-reduced examination protocol for CT-guided cryoablation of renal tumors. They found no significant change in the effectiveness of the dose-reduced protocol but significantly less radiation exposure to the patient [21]. These findings suggest a *high potential* for reducing radiation exposure during CT-guided nephrostomy placement.

## CT-guided puncture

After positioning of the patient in the possible position depending on respiratory capacity, scouting tomography of the area of interest is performed. Dilated collecting systems are well depicted already in noncontrast examinations. If dilatation is not detectable or if there are any suspicious findings in the kidney area like a renal mass then further scans using contrast agent might be performed for better visualization of the region of interest.

Depending on the anatomical relation between the collecting system, stone position, and surrounding structures such as vessels, liver, spleen, or colon the ideal puncture tract is planned. If a laser marker of the planned entry site is not provided by the CT system a skin marker may be placed. The ideal position of the marker is found by repeated scans until a direct transverse tract into the chosen calyx seems possible.

Once the entry point of the needle is defined the puncture site is disinfected and covered by a sterile fenestrated drape. Local anesthesia is administered and the puncture needle is advanced subcutaneously. Repeated scans of the area with usually only three or four 5 mm slices help correcting the needle trajectory until the collecting system is entered and urine can be aspired. A further scan proves the correct position of the needle tip. Afterwards antegrade filling of the collecting system with contrast agent or direct placement of a guidewire is possible. If CT fluoroscopy is available, dilation of the tract and placement of the nephrostomy tube can be performed under direct visual control. Otherwise, further scans prove the correct position of the nephrostomy tip. The tube is secured by a suture. When starting the PCNL a guidewire is placed through the indwelling nephrostomy before dilating the tract and placement of an access sheath. PCNL can be performed directly after CT-guided nephrostomy tube placement or during the days after.

### Outcome

Failure of CT-guided renal access is very rare and some studies even report success rates of 100% [9, 20]. About 80% of the punctures are successful with the first attempt [7, 9, 20, 22]. The need for three attempts is reported in less than 8% [9, 22]. Severe complications such as organ injuries are not reported and bleeding complications are rare. Due to the fact that the cross-sectional imaging enables exact tract planning depending on stone location even in patients with special anatomical situations, CT-guided access was reported in a small series to enable a stone-free rate of 83% after PCNL even with these challenging indications [6].

## Dyna-CT-guided renal access

Most of the punctures performed by urologists can be accomplished safely and quickly by ultrasound alone or in combination with fluoroscopy [23–25]. Ultrasound provides inexpensive, fast, and real-time imaging, but problems include availability in the endourologic suite in some countries, the need for extensive training, and relatively low spatial contrast depending on the abilities of the available system. Common ultrasound machines enable only 2D imaging. Fluoroscopy systems, either C-arm-based or stationary units, are available almost everywhere worldwide to support the performance of endourologic procedures. The main disadvantage of the technique is the lack of soft tissue imaging, the use of ionizing radiation, and only a 2D depiction of the structures of interest. To overcome these problems, new techniques based on 3D imaging have been developed. The Uro Dyna-CT (Siemens Healthcare Solutions, Erlangen, Germany) installed in the endourologic operating suite provides not only standard X-ray and fluoroscopy but also interventional 3D imaging and cross-sectional image reconstruction [23]. It also offers a 3D planning and laser-guiding puncture tool called the syngo iGuide [26]. After having proved the applicability for urologists in cases of complex punctures in a standardized *ex vivo* model [26] the technique was performed sucessfully in complex clinical cases [1].

### Uro Dyna-CT system

The Uro Dyna-CT suite is equipped with an Artis Zee® Ceiling System (Siemens Healthcare Solutions) combined with a customized, full carbon urological examination table and a rotatable flat-panel detector (30 × 40 cm, 48 cm diagonal, 2 k matrix). Post-image processing and 3D reconstruction are performed on the dedicated workstation using syngo MMWP VE 40A 3D reconstruction software (Leonardo, Siemens Healthcare Solutions) [23].

### Urological imaging table

The urological intervention table of the Uro Dyna-CT is a free-floating full carbon table measuring 262 × 52 cm. Additionally, the table enables lateral and cranio–caudal buckling by ±15°. The surgeon can easily control all movements of the table by means of a wireless foot pedal or via the operation terminal that can be covered to render it sterile. The table consists of two parts: the removable distal part (95 × 52 cm) is fixed by an easy-to-use plug socket and can be replaced by stirrups for the lithotomy position. To avoid any interference of metal structures during the imaging process, all parts of the table are made of carbon. The main table and the removable distal part have maximum loading capacities of 250 and 80 kg, respectively. At 19 cm from the distal end of the main table, 23 × 7 cm nephrostomy slots are cut out on both sides to provide perfect access to the renal area in supine position [23].

### Image quality

The ceiling-fixed X-ray system comes with a 30 × 40 cm flat panel detector and moves freely in all directions.

Its maximum rotation speed of 60° per second with up to 495 images per rotation enables complete cross-sectional imaging of the urinary tract and the surrounding tissue within 5–20 seconds depending on the protocol settings. The complete procedure for 3D reconstruction takes less than 2 minutes at any setting [23].

While high concentrations of contrast agent provide excellent imaging quality in fluoroscopic and standard X-ray examinations, they lead to increased streak artifacts in cross-sectional and 3D reconstructions which would reduce the image quality of a Uro Dyna-CT during the intervention. Furthermore, the detection of residual stone fragments can be limited by interference of the contrast agent. Therefore the use of diluted contrast agent is essential to provide good image quality especially for cross-sectional images. Following experimental findings a *20% contrast agent dilution* proved to be perfect for imaging of the urinary tract and radiopaque kidney stones with the Uro Dyna-CT even in obese patients [27]. Similar to undiluted contrast agent, metallic endourological devices are able to cause streak artifacts during cross-sectional and 3D imaging. However, the system can be used for all interventional endourological procedures using the common armamentarium and instruments without significant limitation of image quality. There are only minor limitations according a PCNL working sheath and the rigid URS. These instruments should be removed from the examination field before performing the CT and replaced afterwards using a safety wire [28]. If a plastic Amplatz sheath is used for PCNL it can stay in place for the Dyna-CT scan. In contrast to standard MDCT the image quality of a Uro Dyna-CT depends on the MDCT convolution kernel. As compared with MDCT using a medium-hard convolution kernel, the Uro Dyna-CT produces images at medium noise levels and, simultaneously, medium spatial resolution at approximately the same dose. It is well suited for visualizing hard-contrast objects in the abdomen with relatively low image noise and patient dose. For the detection of low-contrast objects at standard tube voltages of approximately 120 kVp, however, MDCT should be preferred [29].

## Radiation exposure

Although urologists can minimize the radiation dose by tighter collimation and reduction of fluoroscopy time during interventions, the new technical possibilities of the Uro Dyna-CT with CT-like imaging require customized examination protocols for urological needs. On the one hand these protocols have to enable the intraoperative detection of small residual stone fragments and on the other hand they must give surgeons the possibility to detect soft tissue structures such as renal tumors to enable focal therapies or laser-guided biopsies in the future. Therefore customized protocols for urological needs have been developed in a phantom study [30]. The developed and clinically implemented protocols allow for better application of the as low as reasonably achievable (ALARA) principle of radiation protection. The soft tissue protocol causes an effective dose of 7.76 mSv, the stone standard protocol 1.96 mSv, and the stone low-dose protocol 0.33 mSv. The urology stone standard protocol provides excellent hard-contrast imaging with adequate soft tissue depiction, whereas the urology stone low-dose protocol enables sufficient hard-contrast depiction with extremely low radiation dose. Finally this phantom study proved that interventional soft tissue 3D imaging can be performed with an acceptable radiation dose. The image acquisition uses higher radiation doses than the standard fluoroscopy technique. However, it is in an acceptable range compared with standard MDCT examinations. For hard-contrast depiction radiation exposure by the Uro Dyna-CT is even lower than with MDCT.

## Dyna-CT guided puncture

The complete process of a Dyna-CT guided puncture is shown in a video associated with a separate publication [1].

### Image acquisition and puncture planning

For image acquisition, the Artis Zee Ceiling System with a modified imaging protocol is used. Maximum inspiration triggered by the cooperative patient or the anesthesiologist is recommended to enable a reproducible kidney position during the puncture. The Dyna-CT scan is possible with the patient fully covered with sterile drapes as the system's C-arm can be covered, too. Planning of the puncture and image windowing are performed at the dedicated 3D workstation. The most suitable puncture tract to avoid interference with surrounding organs is planned using cross-sectional images and can be checked in the 3D reconstruction for the ideal direction to reach the target, especially for entering a renal calyx (Figure 14.2). The planning software shows the exact length of the planned puncture tract. It also provides an analysis of the ideal C-arm positions to depict the required planes for the puncture.

### Laser-guided puncture

To start the laser-guided puncture, the table is adjusted, and the C-arm is placed in the bullseye position to indicate the puncture site and direction with a laser cross (Figure 14.3). The needle is inserted, keeping the laser cross permanently in an inline position to the needle. During the puncture the anesthesiologist reproduces the same inspiration level as during the initial scan. This is

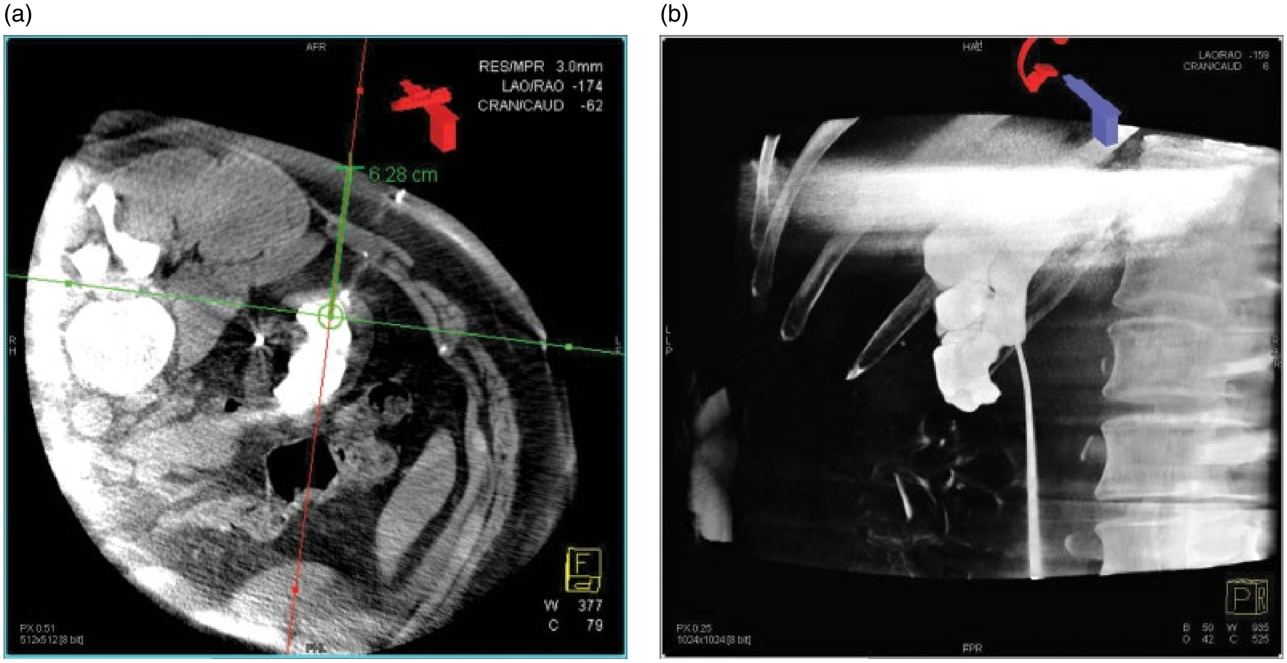

Figure 14.2 Planning of puncture tract with the Uro Dyna-CT in (a) cross-sectional images and (b) 3D reconstruction of the collecting system after retrograde filling with a balloon catheter.

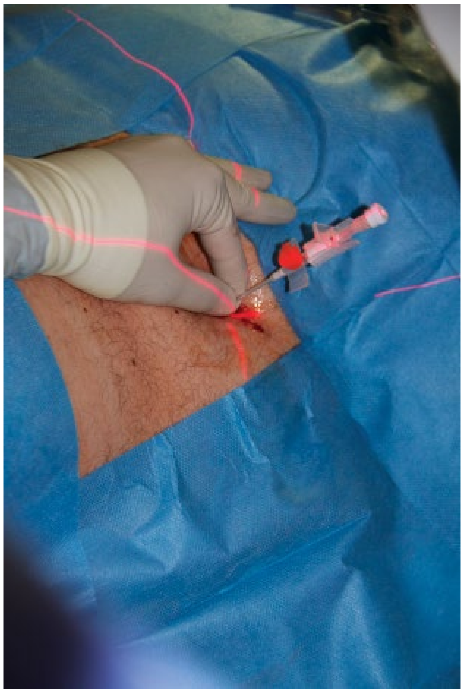

Figure 14.3 Laser cross indicating puncture site and direction during the puncture.

usually controlled by adjusting the same positive airway pressure. The correct placement of the needle can be checked by fluoroscopy. The placement of the needle can be corrected as required by matching it with the indicated road map on the fluoroscopy screen in the bullseye, oblique, and lateral views until the target is reached (Figure 14.4). This road map is provided by the system in any position of the C-arm that might be necessary during the puncture because the Dyna-CT system knows the exact position of the table in relation to the C-arm at any time [1, 23, 26]. When puncturing a renal calyx, fluid excretion through the needle indicates puncture success. This can be additionally checked by antegrade pyelography. When puncturing solid structures as for tumor biopsy, the correct position of the needle can be verified by a customized low-dose Dyna-CT imaging protocol with the possibility of modifying the puncture direction by image overlay with the initial planning data.

### Outcome

Median puncture time for a laser-guided puncture from insertion of the needle to reaching the target with the Uro Dyna-CT is 30 seconds. Median fluoroscopy time during and after the puncture to check the needle position in different angles by the indicated road map on the fluoroscopy screen is 0.7 minutes. Radiation dose caused by the procedure leads to a mean dose area product (DAP) of 96.9 μGy per $m^2$ by fluoroscopy during the procedure and 6113.1 μGy per $m^2$ by the Dyna-CT scan for puncture planning. A total of 24 of 27 punctures (89%) were successful. In two cases a second puncture was necessary and in one case puncture success was achieved after three attempts [1].

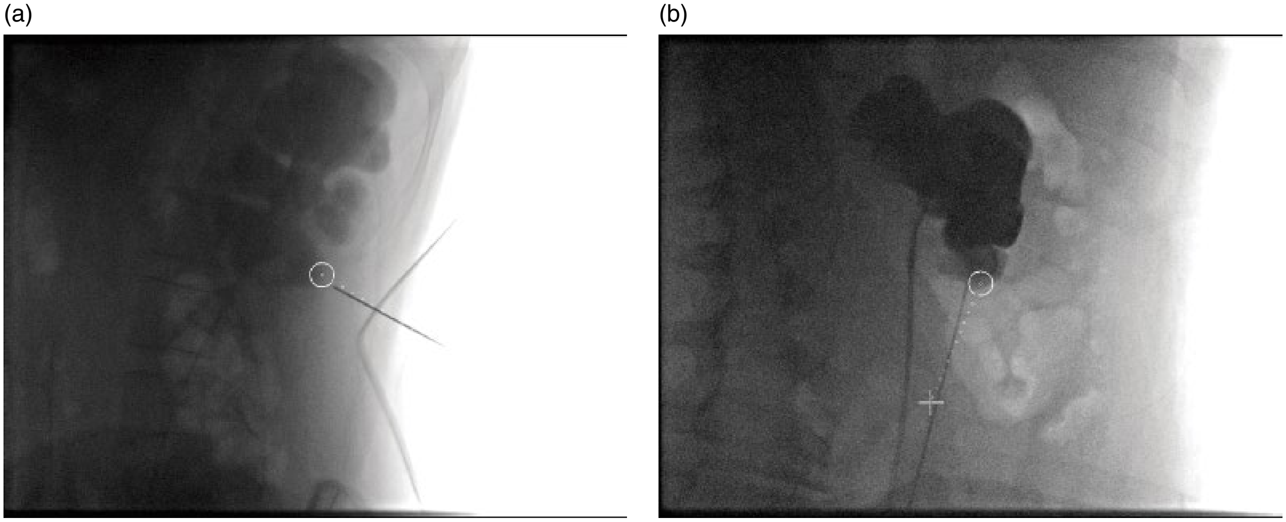

**Figure 14.4** (a, b) Indicated road map of the planned puncture tract on the fluoroscopy screen during the puncture in different planes.

### Limitations

Targets with no or only little movement due to respiration in particular can be punctured successfully with high accuracy. Structures with extensive movement might profit from additional live image acquisition such as with ultrasound or the additional use of electromagnetic tracking of previously placed sensors inside the kidney, for example. Both techniques could be easily combined with the described Uro Dyna-CT puncture technique. The technique is applicable not only for the urinary tract but for any target that can be depicted by the Dyna-CT scan with excellent image quality such as lymph nodes, metastases, tumors, or an abscess. This enables the diagnostic use of the system for gaining histology or therapeutic use for drainage or focal therapy. Image quality of these scans, especially for soft tissue imaging, correlates with the radiation dose exposure of the patient. The radiation dose is naturally higher than with standard fluoroscopy. However, compared with complex punctures with standard MDCT, the radiation dose even might be lower in cone-beam CT-guided procedures as with Uro Dyna-CT. Handling of the system and the guiding software requires specific training, just as other puncture techniques do; therefore, we first evaluated the applicability of the technique in an *ex vivo* biological model. These *ex vivo* experiments are shown in the first part of the supplementary video in [1].

## Conclusion

Both puncture techniques described for gaining access to the collecting system of the kidney before percutaneous stone treatment provide high success rates when they are performed by experienced interventional radiologists (CT-guided) or endourological surgeons (Uro Dyna-CT-guided). As both techniques cause higher radiation exposure to the patient and potentially to the performing surgeon the indication for both techniques should be limited to patients with special anatomical conditions, suspect ultrasound findings, or a history of frustrane punctures with standard techniques. However, with the increasing number of hybrid operating rooms with integrated cone-beam imaging systems, the Uro Dyna-CT technique might become widely available in such medical centers. In these centers the presented technique might be used for selected patients with an increased risk of rare but severe complications such as bowel perforation. For routine procedures the available standard techniques of ultrasound and fluoroscopy should be used. Dyna-CT scans of the patient are possible in the supine position, which might also enable the application of our puncture technique for supine percutaneous lithotomy in complex cases [1, 6, 17, 24, 31, 32].

## Introduction

There has been a dramatic increase in the incidence and prevalence of urolithiasis over the past two decades [1]. Accordingly, there has been a concomitant rise in surgical intervention for urolithiasis [2]. Percutaneous nephrolithotomy (PCNL) is the gold-standard treatment for large kidney stones (>2 cm) [3, 4]. Data from the Nationwide Inpatient Sample (NIS) from 1999 to 2014 demonstrated an increase in the use of PCNL for the treatment of upper urinary calculi [5–8]. Similarly, an analysis of 6 month case logs submitted to the American Board of Urology revealed a 117% increase in PCNL usage from 2004 to 2013 among applicants for Part II board certification [9].

The first description of percutaneous drainage of the renal collecting system dates back to 1865, when Dr. Thomas Hillier reported using repeated renal decompression to relieve symptoms of congenital ureteropelvic junction obstruction in a 4-year-old boy [10]. Ninety years later, in 1955, while attempting an aortogram, Willard Goodwin unintentionally performed the first antegrade nephrostogram by inadvertently injecting contrast into the renal collecting system [11]. Goodwin, turning a "perceived" error into a breakthrough advance, later published his novel image-guided nephrostomy technique in 16 patients with severe hydronephrosis [12]. Over the ensuing decades, the technique for percutaneous nephrostomy has been continuously refined and has thus become widely adopted for both temporary and permanent drainage of the obstructed kidney. In 1976, under fluoroscopic guidance, Fernström and Johannson described the first percutaneous stone removal [11, 13]. In 1984, Smith and colleagues, in a seminal article, described their technique for PCNL in a series of 100 patients, reporting a 5% complication rate and 91% stone-free rate [14]; this cohort was updated in 1985, by which time there were 400 patients with a stone-free rate of just over 94% [15]. Over the past 30 years, PCNL has been further advanced due to the advent of laser and pneumatic lithotripsy, digital endoscopy, and developments in flexible nephroscopy as well as ureteroscopy.

### Endoscopic guided percutaneous access

Obtaining percutaneous renal access presents the greatest challenge during a PCNL. Indeed, de la Rosette and colleagues noted that for a resident to become competent in performing percutaneous nephrostomy, a minimum of 60 cases were needed [16]. Given this requirement, it is not surprising that fewer than 20% of urologists actually gain their own access. However, it is clear that the most crucial part of the procedure is the proper placement of the nephrostomy tract as it determines whether or not the stone can be effectively encountered and cleared.

Due to its challenging nature, multiple modifications for facilitating percutaneous access have been proposed beyond the standard antegrade fluoroscopic approach. Lawson and colleagues were the first to establish a percutaneous tract in a retrograde fashion by puncturing outward from the collecting system to the skin; however, this method proved to be difficult to perform in the presence of a large obstructing pelvic stone and the length/direction of the resulting nephrostomy tract was difficult to control [17]. In 1995, Grasso and colleagues modified the retrograde technique by using ureteroscopic guidance in combination with fluoroscopy to place a percutaneous nephrostomy tract when antegrade fluoroscopic access failed. The technique was subsequently used as a salvage procedure in seven patients [18]. Subsequently, in 2003,

Kidd and Conlin reported similar results using the combined fluoroscopic-endoscopic approach to successfully gain access in three patients for whom the traditional antegrade fluoroscopic method was complicated [19]. Both groups concluded that direct endoscopic visualization of the needle puncture simplified obtaining percutaneous access. While initially considered only as a salvage technique, Clayman and colleagues began to use the combined ureteroscopic-fluoroscopic technique as a first line approach for all PCNL procedures [20].

In this chapter, we describe the combined ureteroscopic-fluoroscopic percutaneous nephrostomy technique as currently employed at the University of California, Irvine. This approach assures a highly precise entry into the targeted calyx. It also may decrease time to access the collecting system, reduce the number of needle passes, lower the radiation dose, and diminish complications associated with purely fluoroscopic antegrade percutaneous renal access.

## Preoperative patient preparation

In all patients, a sterile urine culture is documented within 2 weeks of the procedure. Further, all patients are placed on ciprofloxacin 250 mg twice daily for a week prior to their percutaneous procedure as recommended by Tolley and associates [21]. It is of interest that with this regimen, El Tayeb and colleagues noted a marked decrease in their incidence of postoperative bleeding and need for angioembolization [22]. Also, all patients are placed on a week of tamsulosin 0.4 mg daily to possibly induce a state of ureteral relaxation in order to facilitate deployment of an ureteral access sheath (UAS).

A computed tomography intravenous pyelogram with three-dimensional reconstruction is obtained within 1–6 weeks of the procedure. This is performed with and without contrast, preferably with the patient in a prone position. The transverse, sagittal, and coronal views are carefully reviewed; stone measurements (in three dimensions) and Hounsfield units are recorded. Using the sagittal views, the planned nephrostomy tract to the stone is mapped out such that it will provide the broadest angle of entry to the stone burden; in this regard, the angle between the planned nephrostomy tract and the location of the stone should be greater than 117° to allow passage of the rigid nephroscope and more than 68° to insure calyceal access by the flexible nephroscope [23].

### Box 15.2 Instrumentation list for endoscopically assisted fluoroscopy-guided percutaneous nephrostomy tract establishment

**Permanent operating room equipment**

1) Fluoroscopy-compatible operating room table
2) Spreader bars for the operating room table
3) C-arm fluoroscopy with monitor
4) Video tower setup with light source and television monitor
5) Irrigation system
6) Flexible cystoscope (16 Fr standard)
7) Flexible ureteroscope (7.5 Fr tip and shaft [Karl Storz, Culver City, CA, USA][a] allows use of the Fr UAS; for all other ureteroscopes where the shaft tapers up to 9 Fr or larger a 14 Fr UAS is usually needed)
8) Standard surgical tray (with #11 scalpel blade and Kelly clamps)
9) Holmium laser lithotriptor

**Disposable equipment**

1) UAS
2) 18G nephrostomy needle
3) 5 mm fascial incising needle (Cook Urological, Bloomington, IN, USA) [a]
4) 5 Fr open-ended ureteral catheter (optional)
5) 0.035 inch 150 cm nitinol hydrophilic guidewire
6) 10 Fr Amplatz introducer catheter with 8 Fr obturator (Cook Urological)[a]
7) 0.035 inch 145 cm super-stiff guidewire
8) 0.035 inch 260 cm floppy tip exchange guidewire (male patients only)
9) 1.5 Fr nitinol stone basket for the ureteroscope
10) 30 Fr nephrostomy dilating balloon with 30 Fr renal access sheath
11) 12 Fr Foley catheter
12) 10 ml syringe

## Surgical technique

There are five steps in establishing a successful endoscope-assisted antegrade fluoroscopic percutaneous nephrostomy tract (Box 15.1). Box 15.2 provides a complete list of the instrumentation required for performing an endoscope-guided PCNL.

## Step 1: patient positioning

The procedure begins with the induction of general anesthesia in a supine patient; the patient is then turned prone with his/her legs on spreader bars abducted to 30° (Video 15.1). This position allows the surgeon to have simultaneous access to the affected flank and perineum. In male patients, it is important that the pubis is aligned with the bottom end of the table, which allows the phallus and scrotum to hang free of the table, thereby facilitating male flexible cystoscopy. Cylindrical gel pads are placed on either side of the patient's chest. The patient's legs are padded, fitted with intermittent compression leggings, and then fixed in place with silk tape. The affected flank, external genitalia, and perineum undergo surgical preparation and draping.

## Step 2: retrograde preparation

### Prone flexible cystoscopy and guidewire Placement (Video 15.2a)

The irrigant is attached to the working channel of the flexible cystoscope and irrigant is run through the endoscope to flush all air out of the working channel. Flexible cystoscopy is performed; however, the trigone and ureteral orifices now lie in a superior orientation and one has to "look up" to view them. Accordingly, the cystoscope is deflected upward to identify the intraureteric ridge, which is then followed laterally to identify the affected, ipsilateral ureteral orifice. Provided there is no stone in the ureter, a 0.035 inch super stiff guidewire is advanced into the ureteral orifice and, under fluoroscopic guidance, is passed to the level of the renal pelvis or further cephalad, into the upper pole calyces. It is important to not push the wire to the extent that it coils in the upper pole or else some bleeding may occur. An 8/10 Fr obturator and introducer sheath is then passed. The 8 Fr obturator is removed and a retrograde ureteropyelogram is performed through the 10 Fr sheath in order to outline all of the calyces, and their respective infundibulae. This provides a clear outline of the collecting system and assists in planning the access route to the stone.

If any resistance to passage of the super-stiff guidewire is encountered or if there is a stone in the ureter, then a 0.035 inch hydrophilic nitinol guidewire is used instead of the super stiff guidewire. Once this guidewire is manipulated beyond the ureteral stone and into the renal pelvis, the flexible cystoscope is removed and a 5 Fr angiographic or 8 Fr catheter (from the 8/10 Fr introducer set) is passed over the guidewire until it reaches the renal pelvis. The nitinol guidewire is removed and a retrograde pyelogram is obtained via the 5 or 8 Fr catheter. Next, the 0.035 inch super-stiff guidewire is passed through the 5 or 8 Fr catheter, and the catheter is removed, leaving only the super-stiff guidewire in place. No second guidewire is passed into the system (i.e. there is no designated "safety guidewire").

### Foley catheter placement

A 12 Fr Foley catheter is placed in the bladder alongside the guidewire to ensure proper drainage of urine from the contralateral kidney throughout the procedure.

### UAS placement (Video 15.2b)

For dealing with calculi in the kidney, a 35 cm UAS is selected for the female patient and a 55 cm UAS is selected for the male patient, as the goal is to have the end of the sheath extend into the renal pelvis. The UAS is deployed over the super-stiff guidewire under fluoroscopic control. Initially a 16 Fr UAS (Cook Urological, Bloomington, IN, USA) is passed; if this does not pass easily, then a 14 or 11 Fr sheath is used. The key is to not exert any excessive force on the sheath; "if it don't go easy, it don't go at all" (Louis Kavoussi, personal communication). By adhering carefully to this approach, any significant ureteral damage can be avoided. The UAS facilitates rapid and repeated passage of the ureteroscope, excellent fluid drainage from the kidney, low intrarenal pressure, and spontaneous expulsion of stone fragments during lithotripsy.

### Flexible ureteroscopy (Video 15.2c)

After the UAS is in position, its internal obturator is removed; the surgeon may or may not elect to remove the super-stiff guidewire at this point. If the guidewire has been coiled in the upper pole, it is advantageous to leave it in place as a guide to the upper pole provided that the sheath is large enough to accommodate the guidewire and the flexible ureteroscope. The flexible ureteroscope is advanced through the UAS into the renal pelvis and up into the upper pole calyces. If a stone is blocking the way to the upper pole, then the holmium laser is used to fragment a portion of the stone until a path to the upper pole has been created along which the flexible ureteroscope can then be manipulated into the upper pole calyces.

## Step 3: nephrostomy puncture

### Air nephrogram (Video 15.3a)

Air (3–5 ml) is slowly instilled through the irrigation port of the flexible ureteroscope under fluoroscopic control. Since the patient is in a prone position, the air will flow into a posterior upper pole calyx. The ureteroscope is moved into the air-filled upper pole posterior calyx that is most in line with the upper pole infundibulum and the renal pelvis. In some situations a posterior calyx in the lower pole or a posterior calyx in the midzone of the kidney may be targeted if the situation warrants it (i.e. a bifid system with a lower pole branched calculus).

### Nephrostomy puncture under direct endoscopic visualization (Video 15.3b)

With the C-arm in a cephalad–caudal position (10–15°) for an upper pole puncture (or 10–15° caudal–cephalad for a lower pole approach), the tip of a hemostat or Kelly clamp is fluoroscopically positioned over the tip of the previously positioned ureteroscope in the targeted posterior calyx; if a rib appears to be obstructing the intended path, then the fluoroscope may be moved to a more anteroposterior position or it can be moved further oblique until the rib is no longer overlying the needle's path. A 3 mm horizontal incision is then made in the flank.

Now an 18G percutaneous nephrostomy needle is manipulated under fluoroscopic guidance until it lies "hub over tip" directly in line with the tip of the flexible ureteroscope, which rests in the targeted air-filled posterior calyx. The entire shaft of the needle should appear as a "radiopaque dot" since the entire length of the needle should now be in alignment with the fluoroscopic view. The needle is then advanced toward the tip of the ureteroscope; the goal is for the needle to enter the collecting system directly in front of the tip of the ureteroscope. After the needle has been passed 5–6 cm into the body, the fluoroscope can be rotated 25–30° laterally (i.e. "rainbowed") thereby visualizing the shaft of the needle such that the point of the needle can be monitored as it is advanced toward the tip of the ureteroscope. The entry of the needle into the collecting system should occur as the needle's point crosses the tip of the ureteroscope. If the needle's point is not visualized by the ureteroscope at that time, then there is no reason to advance the needle any deeper; instead the needle is withdrawn, repositioned, and passed a second time, again aiming directly at the front edge of the tip of the ureteroscope. Ideally, the needle's point should be seen to enter the collecting system at the periphery of the papilla or through the fornix. If the needle traverses the infundibulum, it should be left in place and a second needle passed such that it enters the collecting system properly. (Note: if the transinfundibular needle is removed, bleeding sufficient to obscure the field may occur. Also, dilating an infundibular tract runs the risk of significant hemorrhage.)

## Step 4: establishing through-and-through flank to urethral meatus guidewire access

The obturator of the needle is removed. Next, as described by Hoenig et al., a 2.4 Fr nitinol stone basket is passed through the ureteroscope, opened, and advanced over the tip of the nephrostomy needle [24]. A 145 cm guidewire in females, or a 260 cm exchange guidewire in males, is advanced through the nephrostomy needle; the basket is slowly slid off of the needle and then closed on the tip of the guidewire. The guidewire and ureteroscope are then withdrawn through the UAS thereby establishing the through-and-through guidewire.

An alternative method (i.e. the St. Petersburg maneuver as suggested to us by Dr. Nariman Gadzhiev; Video 15.4) is to pass the 145 cm (in females) or 260 cm (in males) 0.035 inch guidewire directly through the ureteroscope and into the open lumen of the nephrostomy needle and then out the flank. This technique eliminates the use of the stone basket, avoids having to withdraw and pass the ureteroscope through the sheath again alongside the guidewire, keeps the ureteroscope aligned on the nephrostomy site for subsequent monitoring of placement of the balloon dilator and the 30 Fr Amplatz sheath, and has the flexible end of the guidewire exit the needle, thereby allowing it to be used for placement of the stent at the end of the procedure.

## Step 5: tract dilation (Video 15.5)

Once through-and-through guidewire access is established, the initial flank incision is extended to 1 cm to accommodate the 30 Fr Amplatz working sheath. A 5 mm fascial incising needle (Cook Urological) is passed over the through-and-through guidewire to incise the lumbodorsal fascia; this precludes buckling of the dilating balloon. Next, under endoscopic visualization, a 10 mm dilating balloon catheter is advanced over the through-and-through guidewire until the balloon just enters the calyx. The balloon is inflated to 16 atm using the Leveen syringe; this too is monitored endoscopically along with a single shot of fluoroscopy to make sure the entire length of the balloon has been fully inflated. The 30 Fr Amplatz working sheath is advanced over the pressurized inflated balloon until the full circumference of the edge of the sheath is seen to enter the collecting system. The dilating balloon is deflated and removed. Now the ureteroscope is removed from the UAS to allow maximum drainage of fragments and irrigant. The rigid nephroscope is passed via the Amplatz sheath into the collecting system and, if stone is not blocking the nephroscope, the position of the UAS is checked. If the opening in the UAS is not in the renal pelvis, then the UAS's obturator is replaced, and under nephroscopic control the sheath is manipulated upward until it rests in the renal pelvis. The surgeon can now proceed with the PCNL.

## Discussion

The combined endoscopic-fluoroscopic approach has the potential to enable the majority of urologists to obtain their own percutaneous access with the highest degree of precision. Previous studies have shown that exclusively using an image-guided approach, be it fluoroscopy or ultrasound, a resident would need to perform 25 and 60 procedures to overcome the learning curve and achieve technical proficiency, respectively [16, 25, 26]. As such, it is not surprising that only 11–16% of urologists in the United States routinely obtain their own access for PCNL [27].

### Advantages

Establishing an antegrade percutaneous nephrostomy using a combination of limited fluoroscopy and endoscopic guidance has many advantages (Box 15.3). First, the surgeon is able to be certain that the needle enters a posterior calyx through the periphery of the papilla or at the edge of the fornix, which are the least vascular points of access. Also the endoscope-assisted technique allows for precise placement of the dilating balloon and positioning of the Amplatz sheath, thereby minimizing parenchymal injury/bleeding due to past-pointing of the balloon dilator or the Amplatz sheath. Further, this approach facilitates placement of a through-and-through guidewire. In addition, by using the ureteroscope and holmium laser, stones blocking or filling the targeted calyx can be cleared prior to needle placement thereby avoiding the situation where the Amplatz sheath is short of the collecting system and irrigant is flooding the retroperitoneum. Moreover, the UAS provides for easy passage of the ureteroscope as well as for drainage of stone fragments and the maintenance of low intrarenal pressures. Ureteroscopy can also be used to inspect those calyces juxtaposed to the nephrostomy tract that would be inaccessible to the flexible nephroscope; this obviates the need for placing a second nephrostomy tract in many cases. Indeed, the flexible ureteroscope is capable of accessing over 95% of the calyces allowing for movement of stones from a remote calyx into the renal pelvis for rapid removal with the rigid nephroscope [28–30]. Lastly this approach is also optimal for obtaining access in the face of a nondilated or markedly distorted collecting system.

Several publications have corroborated the foregoing advantages of the endoscopically assisted approach to nephrostomy tract placement and dilation. Scoffone and colleagues demonstrated the utility of combined retrograde intrarenal surgery with PCNL, reporting needing only single tract access in 98.4% [31]. Similarly, Sountoulides and colleagues demonstrated that compared to fluoroscopic access, combined endoscopy-/fluoroscopy-guided PCNL required significantly fewer access tracts to remove the stone and required fewer subsequent second-look procedures to achieve the same stone-free rate [32]. More recently, Isac and colleagues similarly reported significantly fewer access tracts and secondary procedures when endoscopic guidance was used to obtain renal access [33].

### Reducing radiation exposure

Both patients and healthcare providers are exposed to a significant dose of ionizing radiation during diagnosis, management, and follow-up of stone disease [34]. The endoscopically guided PCNL reduces radiation exposure in comparison to standard PCNL. A contemporary retrospective review of 55 endoscopically guided PCNL cases by Lantz and colleagues revealed that the radiation

**Box 15.3 Advantages of endoscopically assisted fluoroscopic guided percutaneous renal access.**

1) Endoscopic visualization allows for direct visual confirmation that the targeted papilla is posterior.
2) The ureteroscope tip is readily visible on fluoroscopy, providing a clear target for the nephrostomy needle.
3) Increased success of supracostal renal access [32].
4) Reduced fluoroscopy time [33].
5) Visual confirmation of needle placement through the periphery of the papilla or the edge of the fornix.
6) Accurate monitoring of balloon dilation and 30 Fr sheath placement, thereby eliminating injury to the anterior collecting system or to the infundibulum (i.e. no past-pointing).
7) Facilitates securing through-and-through guidewire access.
8) Ability to combine antegrade and retrograde endoscopic manipulations within the collecting system.
9) Retrograde endoscopic access allows entry to portions of the collecting system that cannot be attained readily through the antegrade access.
10) May reduce the learning curve for percutaneous renal access.
11) Decreased risk of pleural effusions requiring drainage [40].
12) Decreased bleeding complications requiring transfusion [32].

dose was reduced by 50–75% versus standard PCNL, regardless of body mass index [28, 35]. Two similar retrospective studies corroborated these findings, revealing a 50–90% reduction in radiation exposure compared with a standard PCNL [23, 32]. These reductions may be further augmented by using low-dose, pulsed fluoroscopy [29, 30]. In 2014, Baldwin et al. reported successful fluoroscopy-free ureteroscopy, showing that tactile feedback, direct visualization, and external visual clues may act as a reliable substitute to fluoroscopy during routine ureteroscopy in selected patients [36]. Applying this approach to PCNL, Alsyouf and colleagues used ultrasound-guided endoscopically assisted PCNL in 20 patients; their results showed comparable operative times, blood loss, and stone-free rates to standard PCNL while reducing radiation exposure by 99% and in some cases eliminating the need for fluoroscopy entirely [37].

### Limitations

There are several drawbacks to endoscope-guided renal access. First, one person (e.g. another surgeon, resident, surgical assistant, etc.) is needed to hold the ureteroscope in position while the operating urologist passes the nephrostomy needle into the collecting system. Second, the use of a UAS and a flexible ureteroscope adds to the equipment and thus the expense of a PCNL procedure. Furthermore, use of an UAS has generated some concern as its passage may result in iatrogenic ureteral injuries [38]. However, large cohort prospective studies have demonstrated that when the appropriately sized access sheath is positioned without excessive force, the incidence of acute injury is minimal [39]. Further there has been no documented increase in post-ureteroscope strictures when the UAS was used [40]. Finally, endoscopically guided PCNL increases the overall operative time by an average of 10–19 minutes [32, 33].

### Complications

The most common complications following PCNL include pleural injury, bleeding, urinary tract infection, fever, and sepsis. Most of the bleeding events are associated with poor placement of the nephrostomy needle followed by tract dilation (i.e. infundibular or lateral to the calyceal fornix). The endoscope-guided percutaneous renal access assures a more precise placement of the needle and hence has led to reduced blood loss and transfusion requirements [32, 41]. Also, while supracostal access is associated, in some series, with a higher stone-free rate, concerns over pleural effusions has limited its use [42, 43]. In this regard, recent studies have shown that pleural effusions with the need for chest tube placement occur significantly less after endoscopically guided PCNL [32]. To date, there are no studies, to the best of our knowledge, examining the infectious complications after an endoscope-assisted versus a totally fluoroscopic percutaneous nephrostomy.

## Conclusion

PCNL is a well-established and effective treatment modality for the management of large kidney stones. Endoscope-assisted fluoroscopic guided percutaneous nephrostomy can enhance the safety and efficacy of PCNL by reducing radiation exposure, improving stone clearance rates and reducing complications while making the procedure more accessible to the urologic community. However, these benefits come at the cost of increased instrumentation, work force, and operative time.

# Percutaneous Nephrolithotomy Access Under Ultrasound

*Mahesh R. Desai & Arvind P. Ganpule*

*Muljibhai Patel Urological Hospital, Nadiad, Gujarat, India*

## Introduction and indications for ultrasound-guided renal access

Percutaneous renal access can be achieved with either ultrasound or fluoroscopy guidance. The method of choice depends on training and personal preference. The side effects of extensive radiation during therapeutic procedures are wellknown, which is the main drawback of fluoroscopy [1]. Ultrasound has several strengths as an interventional tool. It is readily available, relatively inexpensive, and portable. It emitsno radiation and provides guidance for access in multiple, transverse, longitudinal, and oblique planes. Its greatest advantage is use for real-time monitoring of the needle tip, which guides proper placement of the needle and avoidance of important viscera. An added advantage is that it can be used in conjunction with Doppler to avoid important vascular structures lying along the needle path.

Percutaneous ultrasound-guided access is the simplest and most direct technique to drain a hydronephrotic collecting system. It is most often utilized to place a temporary urinary diversion because of an obstructing stone or pyonephrosis. It has also been used successfully to relieve upper tract obstruction secondary to malignancy. Ultrasound-guided nephrostomy puncture is preferred for patients in whom retrograde ureteral access is unsuccessful. It is also a method of choice in pregnancy when there is a need for deobstruction. Allergies to topical or injectable local anesthetic and coagulopathy are the only relative contraindications to ultrasound-guided renal access [2].

The ultrasound-guided approach has proven to be safe and efficacious in the pediatric population [3], for renal stones in transplanted kidneys [4], and in pelvic renal ectopia [5].

Contemporary issues regarding ultrasound as a method to guide access are:

- Who should achieve access:urologists or radiologists?
- How should they be trained?
- Is there is any difference in the outcome for ultrasound- and fluoroscopy-guided access?
- What should be the technique forachieving access? Ultrasound versus fluoroscopy?

In this chapter, we discuss these issues in light of the existing literature. We also describe our technique of achieving percutaneous renal access with ultrasound.

## Instrumentation

### Types of transducer

The "transducer," or "scanning probe" as it is known, is the most important and expensive component of the ultrasound machine. The transducer emits ultrasound pulses and receive echoes during scanning. Ultrasound access requires a dedicated transducer with an ultrasound frequency ranging from 3.5 to 5.0 MHz. The monitor used for intervention should ideally be equipped with an electronic dotted line which shows the needle path. The needle guide that is attached to the ultrasound transducer helps preventdisplacement of the needle from its proper trajectory.

**Sector probes**

The scans from these probes are fan shaped. These scanners can be used when the space for scanning is narrow as they show a very small acoustic window, and are primarily used in gynecologic and cardiac ultrasound. They can be useful when performing nephrostomies in the pediatric age group.

Companion website: www.wiley.com/go/smith/textbookofendourology

#### Convex probes

These probes produce rectangular scans and are most commonly used for gaining percutaneous renal access.

#### Linear array probes

These probes are most commonly used for scanning the breast and thyroid.The ideal transducer for renal access is a convex transducer of 3.5 MHz, focused at 7–9 cm. If such a transducer is not available, then either a linear or sector transducer of 3.5 MHz is necessary. If children or thin patients are to be scanned, then a 5 MHz smaller transducer with a focus at 5–7 cm is required. Alternatively, a sector probe can be used in this situation (Figure 16.1).

### Access needles

Using an 18G needle to access the renal collecting system helps with the introduction of a 0.035 or 0.038 inch guidewire into the collecting system. When ultrasound-guided access is to be achieved, the rigidity of the 18G needle compared to the 21G needle is advantageous for accurately directing the needle tip as it is advanced through the fascial planes. The 18G needle tip is also readily identifiable with realtime ultrasonography guidance.

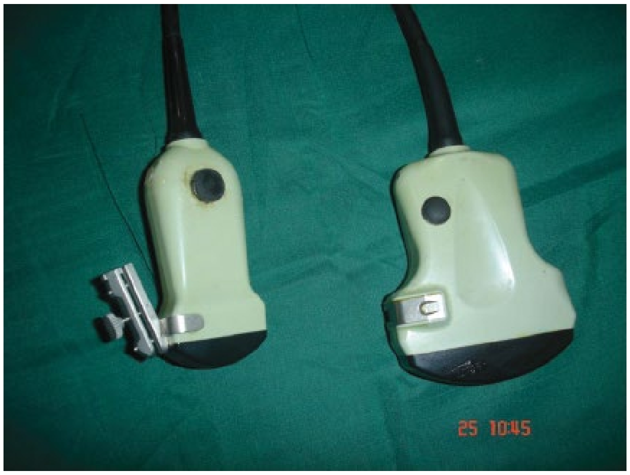

**Figure 16.1** Smaller probes help in gaining access in children. The puncture guide attachment helps direct the needle.

Although routine needles can be used for this purpose, the echo tip needle (Cook Medical, Bloomington, IN, USA) is helpful in achieving ultrasound-guided access; the needle tip is scored and this increases the reflectivity and visualization on ultrasound. The needles are available in three or two parts (Figure 16.2). The three-part needle is useful for instilling contrast after ultrasound-guided puncture as the needle does not need to be removed from the puncture guide. Another variant of the needle has a Teflon sheath which allows instillation of contrast and a guidewire.

## Ultrasound technique

### Orientation and calibration of the image

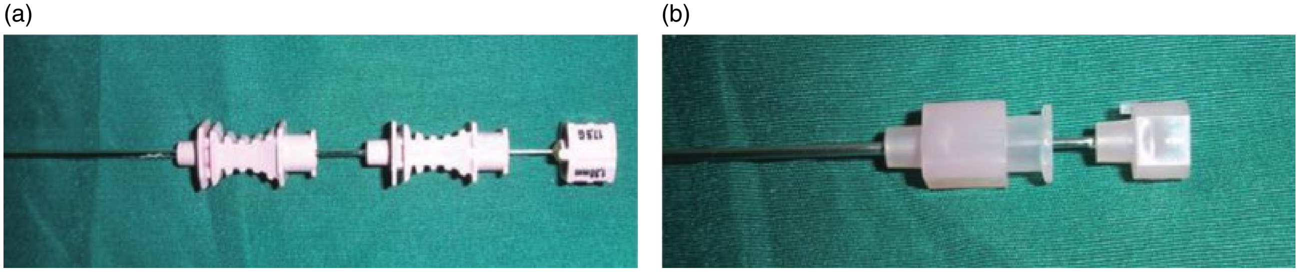
Before starting, it is necessary to visually check which side of the transducer produces which side of the image. Although most of the times there is an indicator on the ultrasound probe for orientation, this is best done by placing a finger at one end of the transducer and seeing where it appears on the screen; if the orientation is incorrect, the transducer should be rotated through 180°. On a renal scan the liver or spleen helps in orienting the upper pole.

The machine should be calibrated properly before use and in such a way that there is a black background with white echoes [6].

### Needle visualization

Clear visibility of the needle is key to the success of ultrasound-guided needle access (Figure 16.3). The most common reason for nonvisualization of the needle tip is nonalignment of the needle tip and transducer. This can be achieved by proper alignment. Although alignment is challenging when done freehand, it will improve with experience and occasionally a mechanical attachment can be used [7].

If the needle is not visualized it may be either off-center or angled away from the transducer. A “bobbing” or “in–out jiggling” movement of the tissue in the superficial



(a) (b)

**Figure 16.2** (a) Three- and (b) two-part needle.

plane helps decide the path of the needle. This movement also helps push the soft tissue away from the needle path and clear visualization of the needle[7].A few other ways in which the needle can be better visualized are by increasing the reflectivity by using large caliber needles, scoring the needle tip (see above), and keeping the bevel of the needle facing upwards.

### Ultrasound-guided access with a needle guide

This is the method of choice for ultrasound-guided access at our center. We use the 3.5/5 MHz probe (Profocus™, B & K Medical, Denmark) with a Doppler attachment. We typically keep one bolster under the patient's lower chest and the other at the level of the iliac crest. We consider that with the patient in the prone position and bolsters in these positions, the bowels and viscera tend to drop down, thus minimizing the chance of bowel injury.

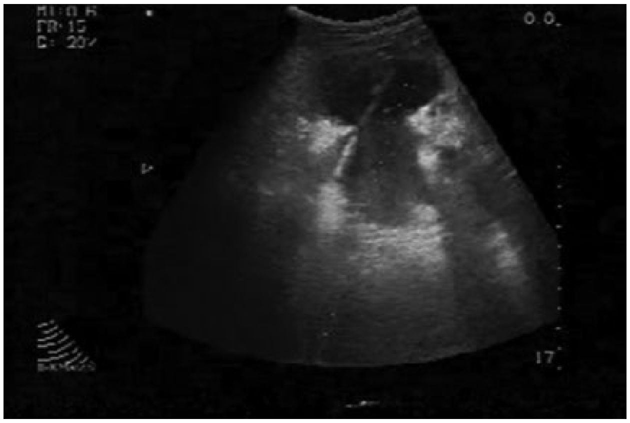


**Figure 16.3** If the needle is aligned properly, then the shaft of the needle is visualized throughout its course.

Ultrasound scanning commences posteriorly and proceeds until the posterior axiliary line. If scanned in this way, the first calyx to be seen will be the posterior calyx. The site of needle entry is marked and the puncture performed with an 18G echo tip (Cook Medical) needle. The key point at this crucial step is that there should be minimal respiratory and ultrasound probe movement. In order to ensure an accurate puncture, the needle tip should be seen along the electronic dotted line throughout its course. The position of the needle in the desired calyx is confirmed with return of clear fluid.

The attributes of a perfect renal access are shortest possible route and a straight tract, traversing the skin, cortex of the kidney, and cup of the desired calyx of puncture (Figure 16.4). We consider that ultrasound-guided access maximizes the chances of this. We have been successfully performing access with ultrasound guidance in percutaneous nephrolithotomy (PCNL) with patients in the supine position; this has also been performed in the pediatric population [8, 9].

### Ultrasound access without a needle guide

Someultrasound transducers do not possess an electronic dotted line or puncture guide. The operator places the probe and scans the relevant renal unit. The probable path of the needle is marked and access is gained. Alternatively, in grossly hydronephrotic kidneys, the ultrasound probe helps with access in the paraspinal area, which is used for opacification of the pelvicalyceal

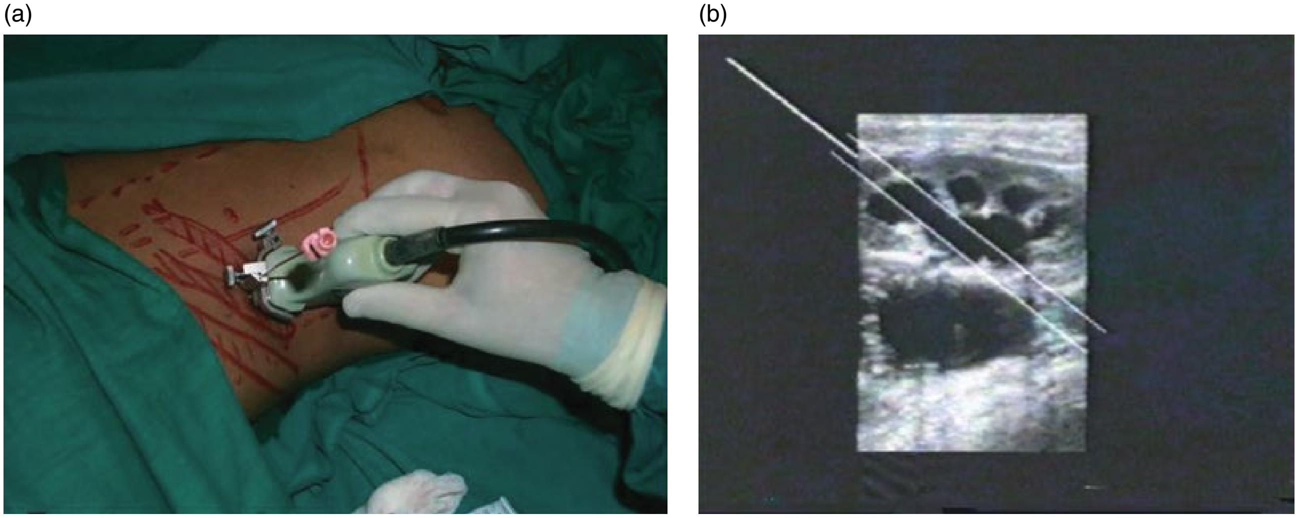

**Figure 16.4** (a) The puncture guide helps in directing the needle in the desired plane and to the correct depth. (b) The ultrasound probe should be aligned in such a way that the tract provides the shortest access from the skin through the cup of the calyx, infundibulum, and finally into the pelvis.

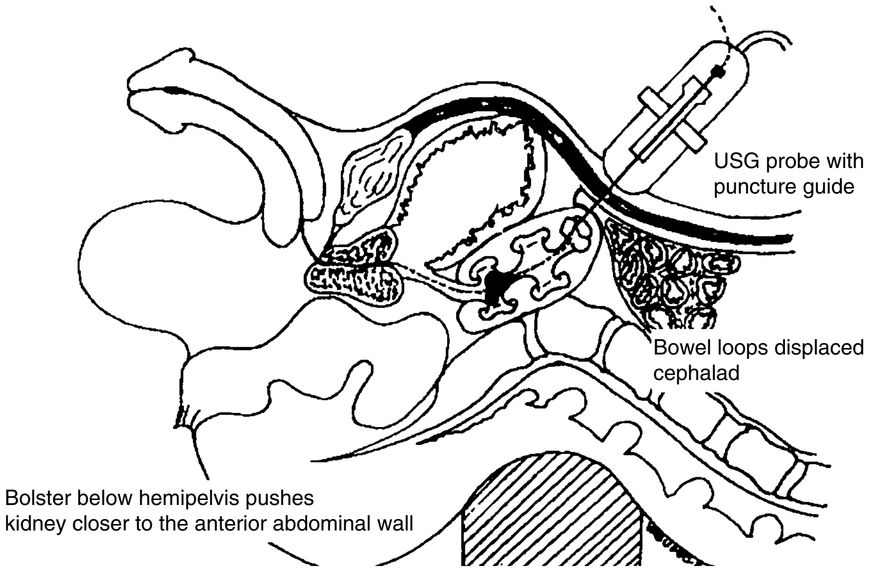

USG probe with puncture guide
Bowel loops displaced cephalad

**Figure 16.5** Technique of ultrasound-guided puncture of a pelvic ectopic kidney. USG, ultrasound guided. Reproduced with permission of Mary Ann Liebert, Inc. Publishers.

system and subsequent fluoroscopically guided puncture in a appropriate calyx.

The serious limitation of the technique is that although the ultrasound probe shows the kidney and calyces, the image is devoid of depth and does not show the plane of the path that the needle traverses; as a result the chance of visceral injury increases. Ultrasound-guided puncture with a Doppler guide is of help in abnormal renal anatomy, such as horseshoe kidney and malrotated kidneys.

## Application of ultrasound in special situations

The various drawbacks of PCNL in the conventional (prone) position include the need to turn the patient from the supine to prone position, risk of tube dislodgments, and neuropraxias. In addition to severe kyphoscoliosis, morbidly obese patients with heart and lung conditions do not tolerate the prone position well. Ultrasound-guided renal access is of value in such situations. Ultrasound-guided punctures are also of value in emergency situations, such as percutaneous nephrostomies in obstructive uropathy in pregnancy [8, 10].

### Ultrasound punctures in ectopic kidneys and transplanted kidneys

The management of calculi in ectopic kidneys is a hotly debated topic, given that a number of treatment modalities, including laparoscopic-guided PCNL, are available. At our center we have been performing PCNL in these cases under ultrasound guidance. Preoperatively the side-to-side mobility and ability to displace the kidney in relation to the abdominal wall is assessed. The site of the puncture is the iliac fossa. A supine oblique position with a bolster under the ipsilateral hemipelvis is used. A mechanical bowel preparation with a low enema is used in all the cases. This helps in identification of gas in the sigmoid colon, which helps identify the bowel and prevents possible injury. Pressure on the ultrasound probe helps to displace the intervening bowel loops between the puncture line and targeted calyx. Similarly, contralateral pressure applied by the assistant helps displace the kidney close to the abdominal wall. All these maneuvers improve the chances of achieving a straight, short, and direct tract to the desired calyx (Figure 16.5).

PCNL is feasible in transplanted kidneys with the help of ultrasound-guided access and this decreases the amount of radiation and intravenous contrast required. With the patient in a left-sided oblique position with a bolster under the ipsilateral hip, the bowel is displaced and a puncture into the superior calyx provides easy access to the ureteropelvic junction and stone in the pelvis [4].

## Preceptorship and mentoring

Competence in ultrasound-guided renal access requires a learning curve to be overcome. The mentoring should start from the residency training itself. At our center training is structured. The trainee initially performs the ultrasound in the outpatient department; later, in the first year of training, they perform ultrasound-guided percutaneous nephrostomies in grossly hydronephrotic systems, and by the end of third year they perform ultrasound-guided punctures for PCNL for renal calculi. We believe this approach shortens the learning curve by giving the trainee insight into the intricacy of aligning the needle with the transducers.

A variety of models have been described for training in ultrasound. Häcker et al. have developed the biologic model using a chicken carcass and fresh *ex vivo* porcine kidney. The laboratory model used routine PCNL equipment. For imaging, ultrasound (7.5 MHz) and a fluoroscopy unit are necessary. This model simulates realistically the clinical procedure of PCNL under ultrasound guidance. In addition, it is low cost and takes little time to prepare, and there are no legal issues involved. The drawback of this model is that it gives no tissue feel and lacks simulation of respiratory movement [11]. Mozer et al. described a system in which the ultrasound image was projected on fluoroscopy. The system consisted of a computer and localizer, allowing spatial localization of the position of the various instruments. Without any human intervention, the ultrasound nephrostomy tract is superimposed in realtime onto fluoroscopic images acquired in various views. In this study the possibility of fusing images derived from two imaging sources was explored[12].

## Urologist or radiologist?

Many urologists do not perform percutaneous access routinely, especially in the United States and some parts of Europe. Despite evidence that urologists can safely acquire percutaneous renal access for PCNL, many centers still rely on interventional radiologists to obtain renal access. In our opinion, the urologist is better suited for making the access. Apart from being technique oriented, their insight into the disease process helps improve outcome.

El-Assmy et al. studied access achieved by a urologist with that by a radiologist; both groups of patients were comparable demographically except that the group treated by the urologist had a higher risk of multiple stones and multiple tracts. The stone-free rates and complication rates were comparable. Multivariate analysis showed that bleeding was not related to whether access was performed by a urologist or radiologist. They concluded that urologists can safely and effectively obtain percutaneous renal access for PCNL as a single-stage procedure [13]. Another study revealed that despite similar access difficulty between groups, access-related complications were less and stone-free rates were improved when a urologist acquired percutaneous access. Urologists trained in percutaneous access may be able to provide improved stone-free rates during PCNL while minimizing access-related complications [14].

To accomplish this, it is essential that the urology residency program should include training in the technique of percutaneous access, as recommended by El-Assmy et al. [13]. It is important to recognize that PCNL has a relatively long learning curve. The fact that kidney puncture and access is a major step for PCNL success highlights the importance of training urologists in this surgical step [15].

## Ultrasound versus fluoroscopy

Access to the renal collecting system with fluoroscopy has the disadvantage of inability to visualize surrounding structures, such as bowel or solid organs, and need for cystoscopy and retrograde contrast instillation for opacification of the system (see also Chapter 12). Percutaneous access with fluoroscopic guidance is more challenging than with ultrasound guidance [16]. The ultrasound-guided approach is safe with a very low risk of major complications. We consider ultrasound is more precise in achieving access, at times, as all the calyces are not filled on opacification.

Level 1 evidence comparing ultrasound and fluoroscopy is scant. In a clinical trial, 100 patients with no abnormality of the upper urinary tract were selected from among candidates for PCNL and randomly assigned to two 50-patient groups: ultrasound-guided access (group 1) versus fluoroscopy-guided access (group 2). Duration of the access procedure was 11 ± 3.5 minutes and 5.5 ± 1.7 minutes in groups 1 and 2, respectively ($P = 0.0001$). Duration of radiation exposure, on average, was 0.69 ± 0.26 minutes and 0.95 ± 0.44 minutes, respectively ($P = 0.0001$). They concluded that access for PCNL using ultrasound guidance is an acceptable alternative to fluoroscopy and decreases radiation hazards [17].

Zegel et al. compared 55 patients with ultrasound access with 33 patients with fluoroscopy access. A significantly reduced number of puncture attempts was noted with ultrasound-guided access (1.2 vs. 4.1) [18], thus significantly reducing the length of time for the procedure.

In our study comparing the two methods of access, the decrease in hemoglobin and hematocrit was significantly less in the ultrasound group [3]. The number of attempts required to achieve a successful puncture was also significantly less in the ultrasound group.

Ultrasound-guided access has also been described in the nondilated system [19, 20]. The fluid infusion

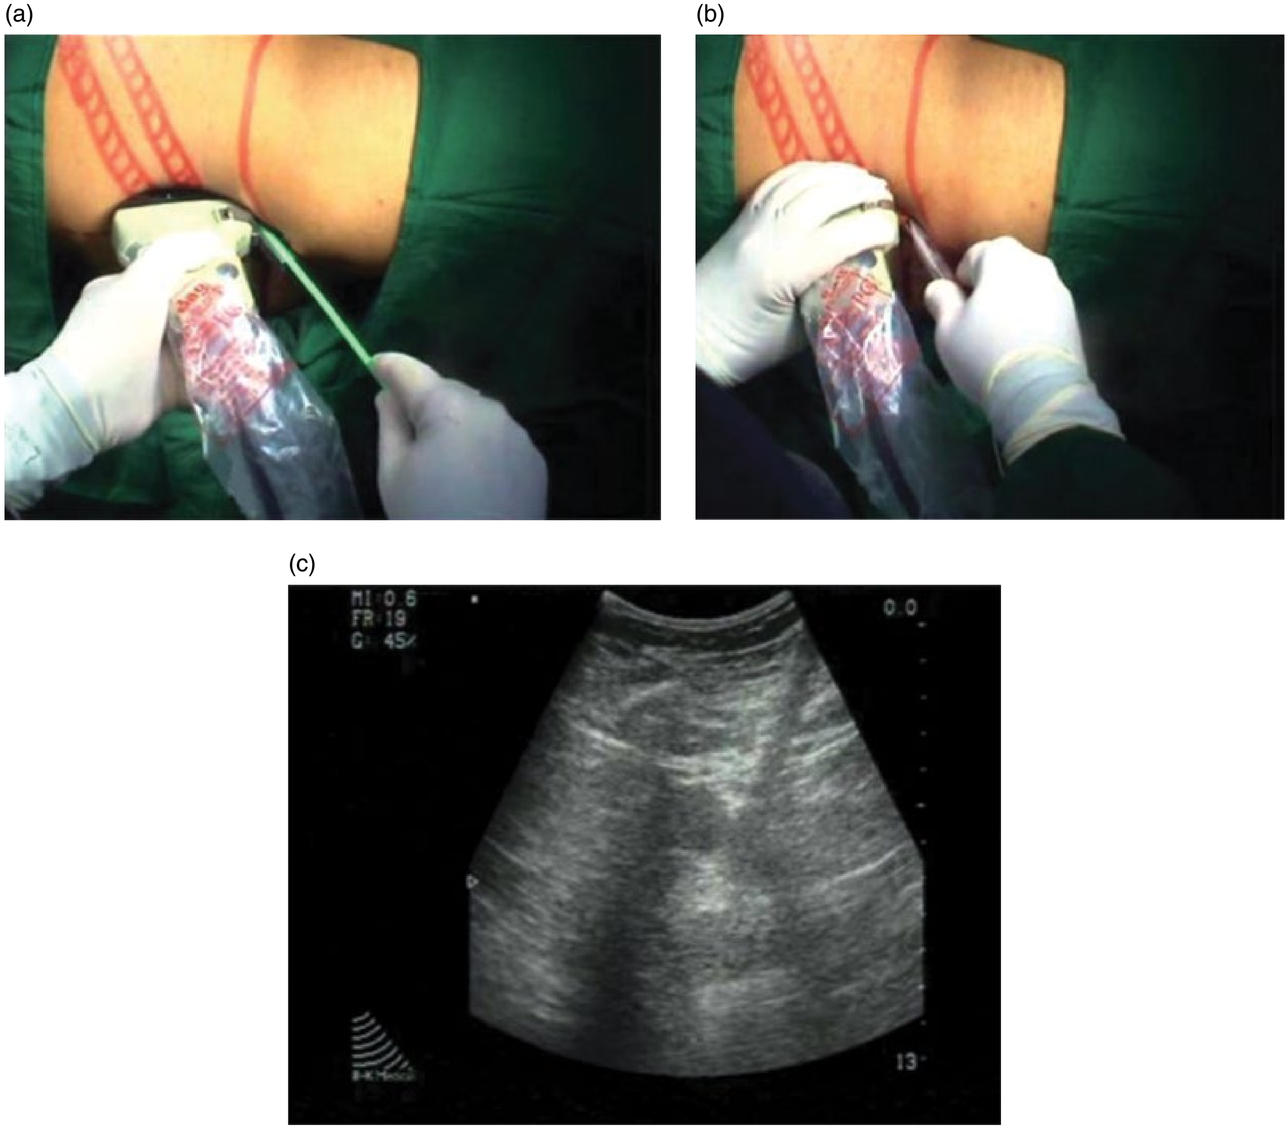

**Figure 16.6** (a) Puncture is performed under ultrasound guidance. (b) The tract is dilated under real-time ultrasound guidance with a balloon dilator. (c) The balloon can be seen under real-time ultrasound guidance.

technique used to make the pelvicalyceal system more prominent has been described to achieve access in such situations [21]. Total ultrasound-guided PCNL has been described [22]. The authors describe that while gaining access the transducer is placed posteriorly whereas during dilation it is placed on the anterior abdominal wall for better visualization of the dilators. Anterior placement is possible as the patients are placed in the flank position. Although feasible, this procedure requires significant experience and the dilators must be visualized throughout the procedure to avoid under- or overdilation (Figure 16.6).

## Conclusion

The role of ultrasound and fluoroscopy are synergistic. Ultrasound-guided access is the method of choice in deobstruction of the upper tract in failed retrograde access, malignancy, and pregnancy. It also helps in PCNL in transplanted or ectopic kidneys. This technique requires considerable experience and training in it should be structured and begin in residency.

Video 16.1 demonstrates the technical aspects of gaining ultrasound-guided access to the collecting system.

## Introduction

Nephrolithiasis is a common clinical problem, and its prevalence has increased over the last 30 years [1]. In the United States, it has a prevalence of 8.8%, affecting one in 11 people, being more prevalent in males (10.6%) than in females (7.1%) [2]. Given the high prevalence of this disease, various forms of treatment have been developed and applied over time [3], such as open surgery, percutaneous nephrolithotomy (PCNL), extracorporeal shock-wave lithotripsy, and, more recently, flexible ureterorenoscopy [4, 5]. However, of all these forms of treatment, PCNL, first described in 1976 by Fernstrom and Johansson [6], is the best for bulky kidney stones [7, 8]. The guidelines of the European Urology Association recommend PCNL for the treatment of renal calculi larger than 2 cm and lower pole renal calculi larger than 1.5 cm [7]. PCNL comprises several main steps: insertion of a ureteral catheter in the renal pelvis with dilation of the pyelocaliceal system, percutaneous puncture of a renal calyx, passage of a guidewire, tract dilatation, placing of Amplatz sheath, nephroscope introduction and ultimately, calculi fragmentation and fragments removal [9]. In all these surgical steps, percutaneous puncture of the renal collecting system is the most difficult step, which causes more complications and which influences more the subsequent success of the procedure [10, 11].

Fluoroscopy and ultrasound, alone or combined, are the most used methods to guide the puncture of the renal collecting system [12]. However, these methods have a steep learning curve and continue to be a major cause of morbidity [10, 11]. To overcome these important limitations, new methods and techniques have been introduced to improve the quality of renal puncture during PCNL, since the modification of patient position to the use of new instruments to guide the puncture [13]. These methods include an optical system incorporated into a needle [14]; marker-based Apple iPad-assisted puncture [15–17]; puncture assisted by electromagnetic sensors [15, 16, 18, 19]; laser-assisted puncture through three-dimensional (3D) computed tomography (CT) using Uro Dyna-CT [15, 16, 20]; and ultrasound using the SonixGPS navigation system [21, 22]. The increasing use of computer programs to assist in the use of these new approaches should be noted.

This chapter will review the new techniques developed for puncture of the renal collecting system, in order to verify the advantages and disadvantages of each and understand which technique has the greatest potential to become the future gold standard of PCNL.

## Classic techniques for renal collecting system puncture: fluoroscopy and ultrasound with direct endoscopic visualization

Classic percutaneous access techniques to the renal collecting system in PCNL comprises, most commonly, the use of fluoroscopy and ultrasound [8]. Fluoroscopy and ultrasound can be used alone or in combination, acting as if in synergy [23–25]. When using fluoroscopy, the procedure begins with placing a urethral catheter in the renal pelvis to opacify and extend the pyelocaliceal system [23]. The image obtained by this method allows an excellent characterization of the renal excretory tree in real time, but has the disadvantages of giving a view

only in two dimensions (2D), causing exposure to ionizing radiation, and being highly dependent on the technical skills of the surgeon [23, 26]. Ultrasonography is a technique that allows real-time direct visualization of the structures involved in the puncture, being useful to prevent damage to adjacent structures in addition to serving as a guide to the needle, and it has also the advantage of there being no exposure to ionizing radiation. However, as with fluoroscopy, it is highly operator-dependent, requiring great experience for its correct use, especially in situations involving a lack of expansion of the pyelocaliceal system. In addition, the images are displayed in 2D, and correct visualization of the needle can be impossible in cases of obesity or a patient's anatomical deformities [24, 26]. In an attempt to improve access in PCNL, these two techniques (fluoroscopy and ultrasound) were combined. a combination of these techniques allows a higher success rate. This combination does not eliminate exposure to ionizing radiation, but reduces significantly the radiation exposure time [25].

In an attempt to minimize exposure to ionizing radiation and improve the accuracy of access to the renal collecting system, Alsyouf et al. [27] proposed a technique that involves combining ultrasound with direct endoscopic visualization. In this technique, the surgeon chose the ideal calyx to puncture through real-time visualization by ureteroscopy, wherein ultrasound was used to guide insertion of the needle. The ultrasound identifies the correct calyx through the movement caused by the ureteroscope deflection, and also helps avoid injury of the adjacent anatomical structures. If the needle is not centered in the calyx then small adjustments can be made under direct visualization by ureteroscope. This technique has the advantage of reducing the routine use of fluoroscopy. However, the procedure presents some disadvantages, such as the large technical capacity that is mandatory for ultrasound and the difficulty of its use in obese patients, in patients with anatomical abnormalities, and in poorly dilated pyelocaliceal systems [27].

## New technologies for puncture of the renal collecting system

### Optical system incorporated into a needle

In this system, the needle used to puncture the renal collecting system has an optical system incorporated that allows visualization of the renal collecting system in real time through a monitor, thereby eliminating the use of fluoroscopy. Access to the pyelocaliceal system is obtained by visualization of structures by conventional ultrasound. The skin is punctured in the posterior axillary line, and the punctured calyx is the posterior inferior calyx. This whole process is performed with the patient in the prone position. The optical puncture needle has been used in 15 patients and the objective was to describe the use of a micro-optical system through a specific puncture needle to confirm the quality of the chosen access. The puncture had to be repeated in four of 15 patients [14].

The great advantage (Table 17.1) of using this puncture system is that it allows secure identification of the needle's location within the renal collecting system immediately after entry, helping to clearly identify the position within the renal system, facilitating handling and learning. Thus, it enables fluoroscopy to be dispensed with, and for the procedure to be free of ionizing radiation. Visualization of needle entry is made in real time by ultrasound. On the other hand, this system does not allow the redirection of the needle in cases of path error, and it does not help in creating a correct path to the puncture and it does not improve the quality of access to the puncture, which as we have seen is a very important feature of PCNL (Table 17.1). Other disadvantages (Table 17.1) are also associated with the use of ultrasound, for example the 2D image, difficult visualization in obese patients, and being highly operator-dependent [14].

### Marker-based iPad-assisted puncture system

Prior to the surgical procedure itself, the pioneers of this technique performed a CT with multiple sections, with the patient in the prone position and at the final stage of inspiration, taking into account that this position must be equal to the position of the patient during PCNL. The CT images obtained in this way are analyzed by computer, becoming 3D images of patient anatomy. Thus, any anatomical detail of the patient is shown in 3D, and is useful for surgical planning, including the choice of the puncture site, as a guide during surgery. In order to decide upon optimal access to the collecting system, during preoperative CT five colored radiopaque markers are fixed around the target area for puncture execution [17]. During the course of PCNL, an Apple iPad is used as a camera, computer, and monitor [15, 16]. With the patient under general anesthesia and in the same position in which the preoperative CT was performed, the iPad camera is pointed toward the patient and, using a WiFi network, the images of the patient in surgery transmitted by iPad are merged with the virtual 3D images of the preoperative CT (Figure 17.1). For this merging process, it is necessary that at least four markers are visible to the camera, in order to provide a correct access position. This whole process is continuous and allows an augmented reality of the patient's anatomy, giving a virtual view from inside the patient. Since preoperative CT scan is performed at the end of inspiration, the anesthesiologist must stop the patient breathing at the end of inspiration to allow the puncture to be performed in the

**Table 17.1** Advantages and disadvantages of new renal colleting system punctures techniques.

| Technique | Advantages | Disadvantages |
|---|---|---|
| Optical system incorporated into a needle | Secure identification of the needle's location within the renal collecting system<br>Facilitated handling and learning<br>Technique is free of ionizing radiation<br>Real-time needle visualization on puncture by ultrasound | Does not allow the needle redirection in cases of error trajectory<br>Does not help in creating a trajectory<br>2D image<br>Visualization difficulties in obese patients<br>Operator dependence |

provided space. Then, a puncture is performed using the virtual 3D image provided and a 2D digital fluoroscopy image in real time, to enable final adjustments.

This technique has been performed in a preclinical phase with human phantom with a calculated error of 1 mm. Clinically, it was performed in two patients with complicated nephrolithiasis with indications for PCNL. Both punctures were performed successfully, defined by the needle reaching the desired calyx [17]. Later, the same procedure was performed *in vitro*, which showed a significantly higher time for realization of puncture in expert surgeons, compared with the conventional techniques of fluoroscopy and ultrasound. However, in trainee surgeons the technique significantly reduced the time of exposure to radiation. After the *in vitro* trials the technique was applied in 19 patients and was performed

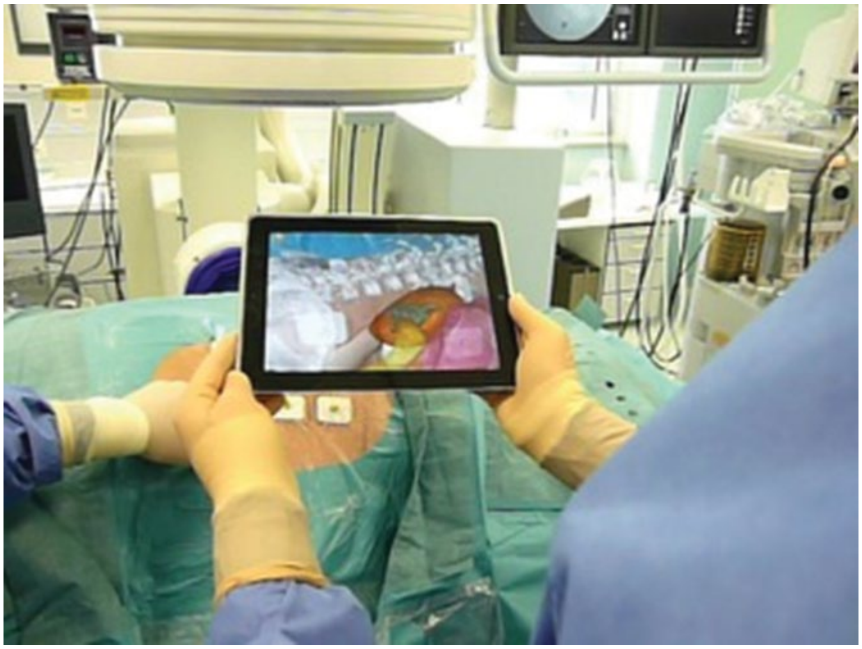

**Figure 17.1** Marker-based iPad-assisted puncture. Determination of the puncture site using an iPad and 2D fluoroscopy.

on the first attempt in 13 of 19 patients (average 1.5) with a radiation exposure dose of 377.5 μGy per m$^2$ [15, 16].

The marker-based iPad-assisted puncture system shows the following advantages (Table 17.1): correct selection of the location and angle to the puncture with good definition of the path, a better anatomical knowledge of adjacent organs with 3D image, correct visualization of patient anatomy regardless of anatomical conformation, minimal space errors, and decreased time to puncture in trainee surgeons. The disadvantages (Table 17.1) are associated with the following: use of ionizing radiation, absence of 3D image in real time, increased puncture duration in expert surgeons, only minimal adjustments in the path, and the patient being in the prone position [17].

## Electromagnetic tracking sensors

This technology was initially tested in *ex vivo* [26] and *in vivo* models [18]. In this last model, pigs were placed in the supine position, an electromagnetic field generator was placed near the pig, and a rigid cystoscope was inserted with the goal of identifying the ureteral opening of the two kidneys. Subsequently, a ureterorenoscopy was performed allowing the placement of a ureteral catheter in the desired calyx. The ureterorenoscope tip was positioned in the desired place to the puncture by direct viewing of a camera. Through an electromagnetic sensor located at the tip of the needle and an electromagnetic sensor located at the tip of the catheter, a virtual path was created from the relative orientation and position information provided in real time by needle and catheter electromagnetic sensors (Video 17.1). Using the 3DPuncture software (created for this project) the virtual path in 3D was shown to the surgeon, which confirmed that the catheter and the needle were aligned in parallel (Figure 17.2). The surgeon can redefined the orientation of the catheter when desired, and a new virtual trajectory calculated when necessary. This procedure provides real-time positioning to the surgeon, allowing a perfect orientation of the needle to be maintained constantly even in the presence of anatomical deformities. The confirmation that there are no unwanted anatomical structures at the puncture path is checked by ultrasound.

Six female pigs were subjected to the indicated procedure, and four punctures were performed by two surgeons in each animal, including one in the kidney and one in the middle ureter, on both sides. In order to certify the technical quality, the number of attempts and the time required for evaluating the virtual path and performing percutaneous puncture were monitored. A total of 24 punctures have been successfully carried out, 12 through the middle ureter and 12 in the renal calyces. To assess the trajectory of the puncture in the ureter took an average of 15 seconds, while in the kidney it took 13 seconds ($P = 0.1$). The average time for the kidney puncture was 19 second, and 51 seconds in the ureter ($P = 0.003$). Between the expert and the trainee surgeon there were significant differences in puncture planning time, with a shorter time for the expert ($P = 0.03$) [18].

Recently, the first clinical experience with a novel navigation system using electromagnetic guidance (IDEAL Stage 1) was described [19]. In this procedure, the patient

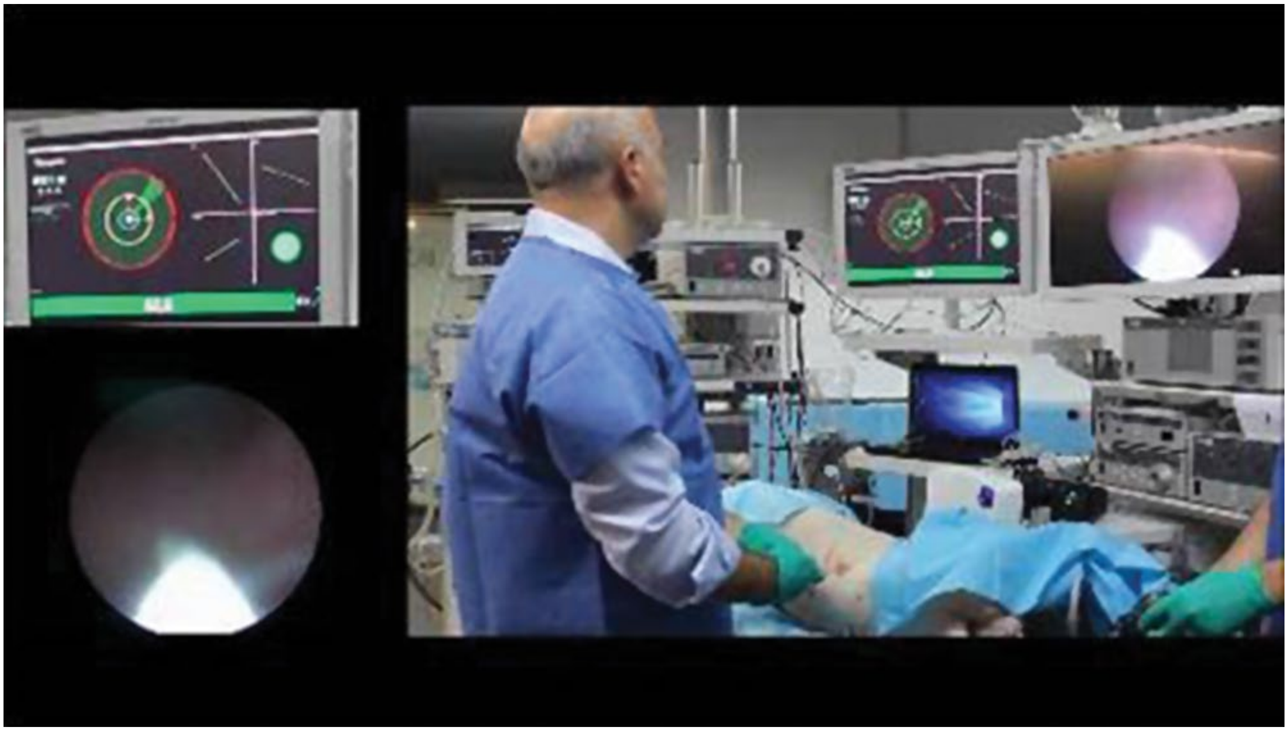

**Figure 17.2** Renal collecting system puncture using electromagnetic sensors. A research group from the University of Minho, Braga, Portugal, patented a new navigation system with an easy-to-use visual system.

is placed in the supine position to allow a combined approach with flexible ureterorenoscopy and percutaneous nephroscopy. An electromagnetic field generator is placed near to the patient to create a field that allows the position of the catheter and needle sensors to be seen. After that, an ureterorenoscope is inserted, with the identification of the ureteral meatus and insertion of a hydrophilic guidewire through it. Next, a digital videoureterorenoscope is inserted, guided by the hydrophilic guidewire to the renal pyelocaliceal system, and the guidewire is extracted. Subsequently, the ureteral catheter with an electromagnetic sensor is inserted through the flexible ureterorenoscope working channel. After choosing the most appropriate renal calyx for percutaneous puncture and carrying out an ultrasound scan in order to verify that the path of renal puncture is not obstructed by any unintended anatomical structure, percutaneous puncture of the selected calyx is done, guided by real-time 3D images observed on the monitor (Figure 17.3). Next, the percutaneous renal puncture tract is dilated, followed by placement of the dilatation balloon and the placement of an Amplatz sheath. This whole process is done without the use of fluoroscopy, only by monitoring of the videoureterorenoscope image. Finally, a nephroscope is inserted via the Amplatz sheath, followed by fragmentation and extraction of renal calculi.

This technique has the following advantages (Table 17.1): lack of exposure to ionizing radiation; real-time 3D image of the needle trajectory; correct needle placement and orientation in real time; greater ease of technical learning (learning curve of 12 cases); execution time significantly decreased; possibility of redefining the trajectory; the catheter was constantly monitored by an electromagnetic sensor and by the fiberscope camera, allowing the surgeon to make minor adjustments and complex navigation maneuvers; real-time monitoring of anatomical changes; the entire procedure could be performed in the supine position, eliminating the need of repositioning, thus reducing the surgery time in 30–40 minutes, while increasing the patient and surgeon comfort levels; no interferences were detected in electromagnetic field. The disadvantages (Table 17.1) associated with this new technique are: as in fluoroscopy, there is a lack of visualization of anatomical structures in the puncture tract, and possible difficult placement of the ureteral catheter bearing the electromagnetic sensor in the desired calyx in situations when the calyx is fully occupied by a calculus [19].

### 3D CT using Uro Dyna-CT

Uro Dyna-CT (Siemens Healthcare Solutions, Erlangen, Germany) corresponds to a modified angiography unit,

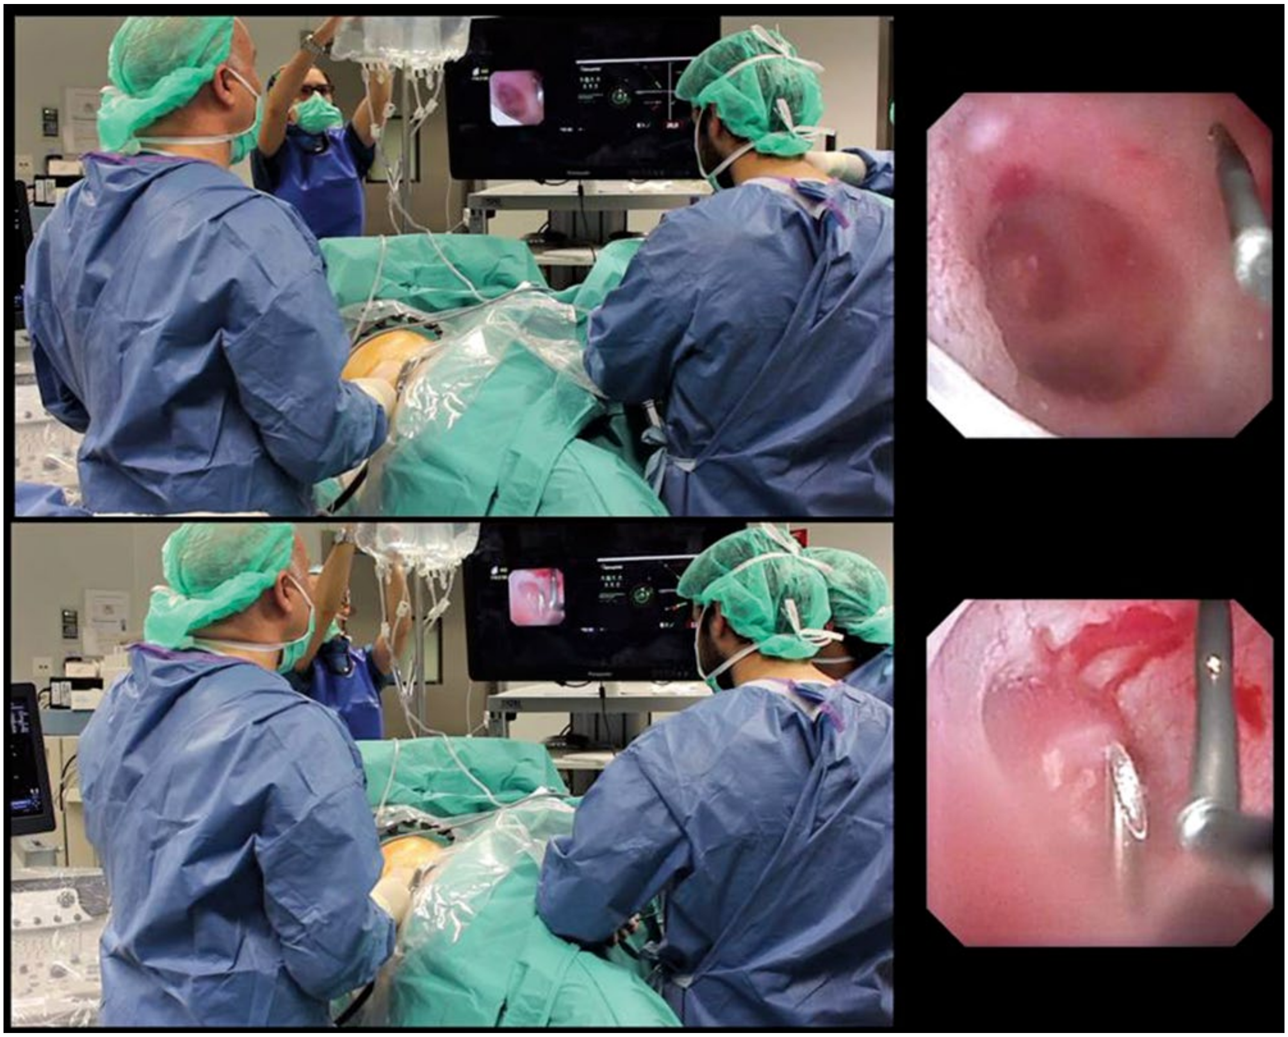

**Figure 17.3** Guided by the 3D navigation software system on the monitor and confirming simultaneously with the ureterorenoscope image, the surgeon performs a puncture of the lower calyx during human PCNL.

allowing the fluoroscopic unit to be rotated around the patient, creating a similar image to the images created by CT (Figure 17.4). The segmentation of the acquired data enables 3D multiplanar reconstruction of the renal collecting system, which is filled with contrast [15, 16]. From a reconstruction of this kind, the best puncture path, avoiding interference from other organs and coming to the desired position, can be created. The planning software shows the exact path chosen for the puncture [15, 16, 20]. The C-arm is placed in the bullseye position to indicate the puncture site and its direction, using a laser light that is oriented (based on the 3D reconstruction) for the path that the needle must take for correct execution of the puncture. Then, the needle is inserted into the predetermined site, keeping it in line with the laser light during the entire procedure to ensure the correct angle. At the end of needle insertion, positioning is confirmed by conventional fluoroscopy. The needle positioning can be corrected if necessary by combining its position with the puncture map displayed on the fluoroscopy screen, in bullseye oblique and lateral view, until the desired target is reached.

The Uro Dyna-CT system allows the surgeon to know the exact position of the table relative to the C-arm at any time, and the map is always available (Figure 17.5). During the puncture of the renal calyx, excretion of fluid through the needle indicates success. In addition, success can be further confirmed with antegrade pyelography under fluoroscopic control. This procedure was applied to 12 patients and was performed by a single surgeon [20]. The cases selected for this technique were instances where the puncture by conventional approach failed or in complex situations. Puncture success was documented and it was successfully performed in nine of the 12 patients (in two patients contrast fluid extravasation occurred and in one the procedure could not be

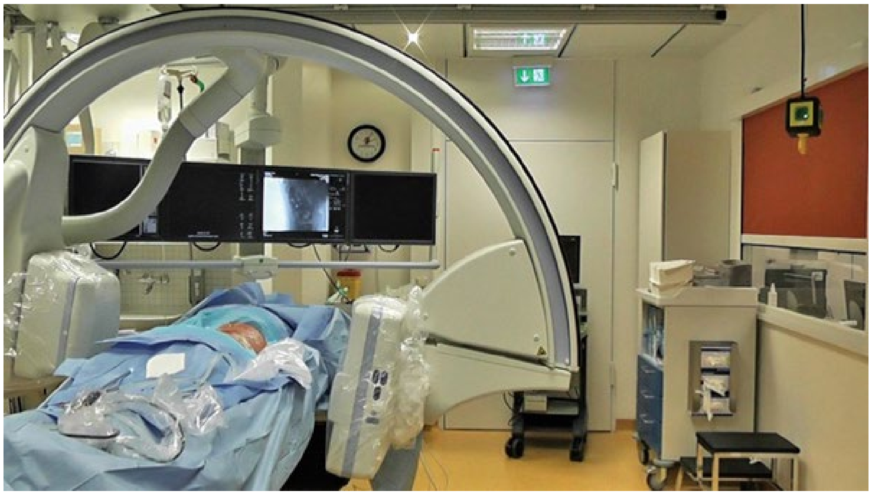

**Figure 17.4** 3D CT using Uro Dyna-CT for laser-assisted puncture during PCNL. Reproduced with permission of Marie-Claire Rassweiler.

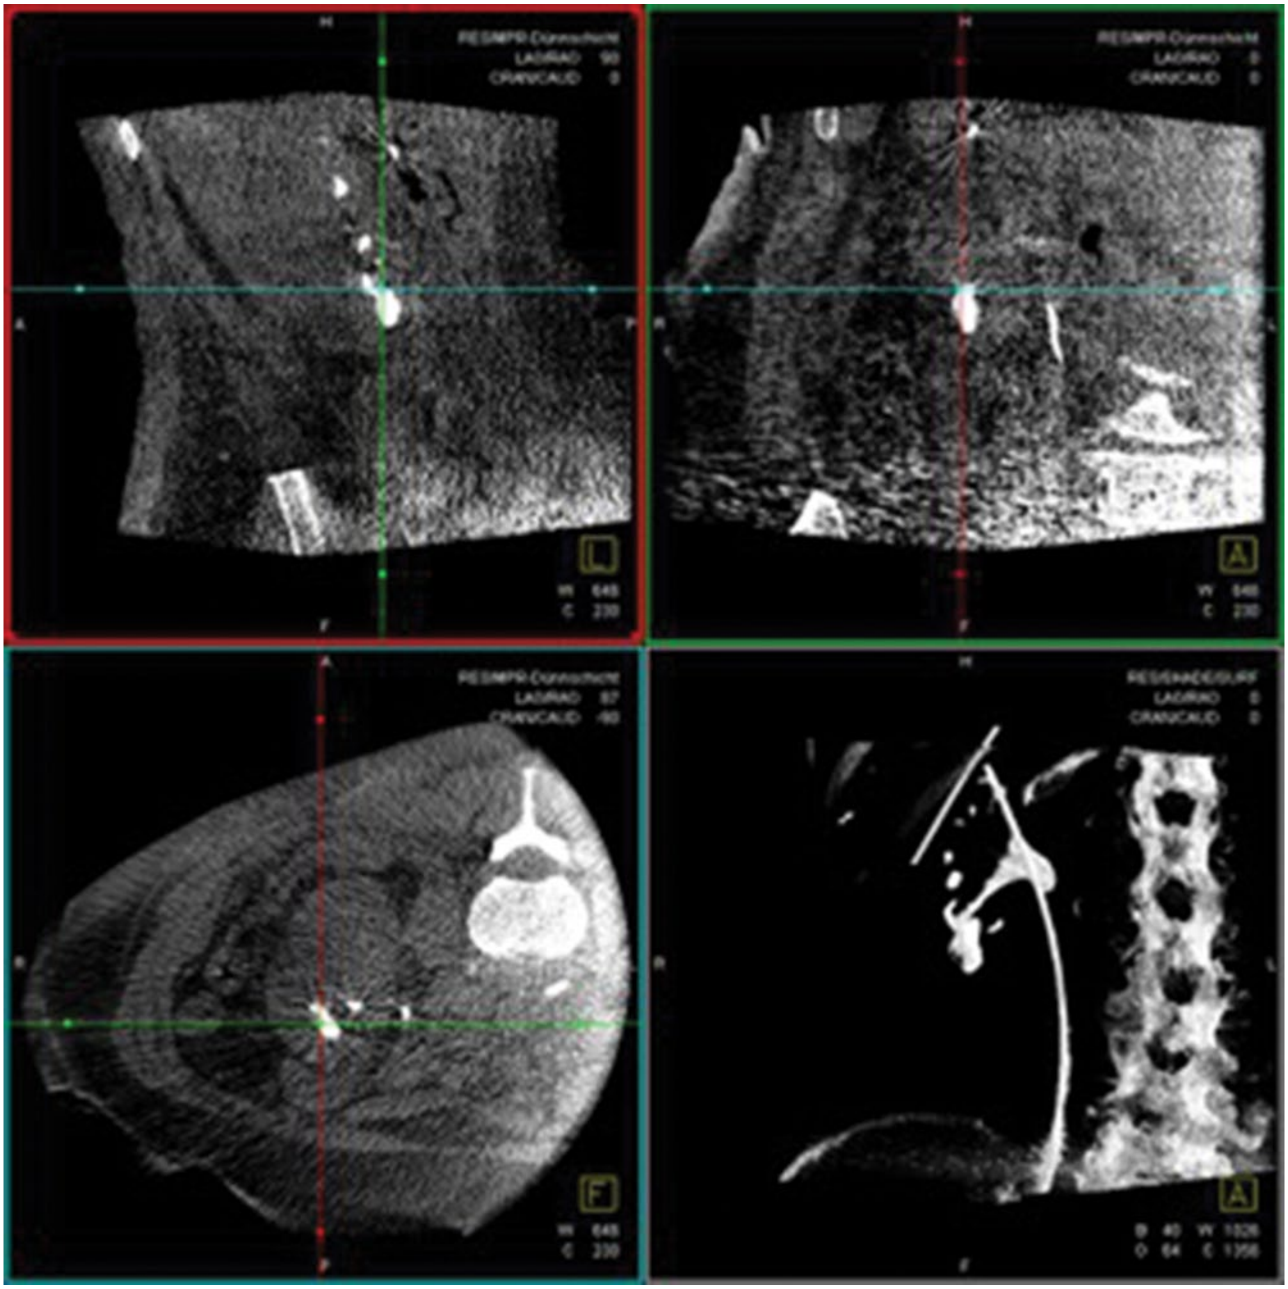

**Figure 17.5** Planned puncture tract to the renal calyx before PCNL.

performed due to renal hypermotility). In the nine in which the puncture was performed, seven punctures were done on the first attempt. The average puncture time was 60 seconds with an average planning time of 6.5 minutes, and an average dosage of exposure to radiation of 5850 µGy per $m^2$ [20]. This system was also used in an *in vitro* experiment, in which they were made 10 punctures, with nine punctures performed successfully, eight of which on the first attempt [15, 16].

This technique had the following advantages (Table 17.1): 3D anatomical image; fast, safe, and highly accurate when there is no patient movement; great definition of crossed structures, and ability to be performed in complicated cases (with a heterogeneous sample of patients); real-time path visualization; it is possible to change the trajectory if the needle is in the wrong position, because the trajectory is always available in real time; the patient can be in the supine position. However, this technique presented some disadvantages (Table 17.1): ionizing radiation dose was higher than with conventional techniques; excessive renal motility hampered the performance of the technique; the learning curve was steeper than with other techniques; and the cost is higher than with the other described techniques [20].

## Ultrasonography using SonixGPS navigation

Initially, a catheter is inserted via cystoscopy in the pyelocaliceal system with the patient in the lithotomy position. Then, with the patient placed in prone position, saline is instilled in the pyelocaliceal system to distend it. Subsequently, a global positioning system (GPS) electromagnetic transducer is placed at a location near the patient, and adjusted for good signal strength. In order to evaluate the path for the needle to follow, as well as the size and location of the stone and the kidney anatomy, an ultrasound scan is performed with the SonixGPS ultrasound probe in the area of the 11th and 12th rib edges. The observed images on the monitor acquired from the SonixGPS probe demonstrate the proper position and direction of the needle during the puncture. The direction, depth, and needle insertion angle can be adjusted as needed, according to the information available in real time through the needle sensor. Thus, using the images obtained through this technique, the needle with an incorporated electromagnetic sensor can be guided to the predetermined calyx (Figure 17.6) [21]. This technique was applied in 25 patients with a kidney stone [22]. The most important assessed outcomes were

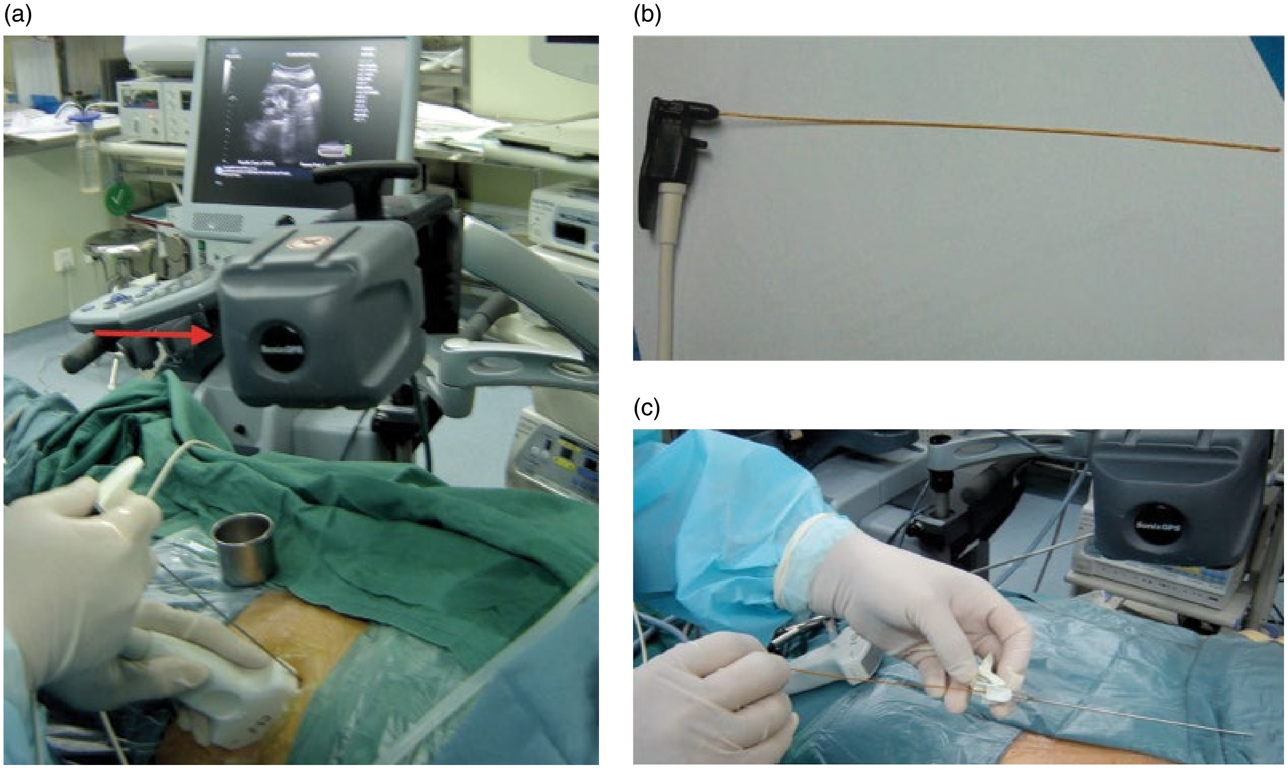

**Figure 17.6** SonixGPS needle tracking system in PCNL. (a) The transducer, which contains a positioning sensor (red arrow), is placed close to the operation area to ensure tracking and positioning of the needle. (b, c) When the electromagnetic sensor filament (b) is inserted into the GPS needle, the electromagnetic signal of the needle can be tracked and guided by the system. Reproduced with permission of Hui He.

the time required for the puncture and the success rate. It should be noted that this technique was performed successfully only with one attempt for each patient. The average puncture time was 5.5 minutes and patient stone-free rate was 92% [22].

The main advantages (Table 17.1) associated with the use of this technique are the following: absence of ionizing radiation; it can predict the trajectory of the needle prior to puncture, providing information on the depth, location, and insertion angle of the needle, allowing the operator to select the safer direction to the patient; it had provided and predicted the needle tip position at all times on the ultrasound screen, allowing the user to use ultrasound image to advance the needle correctly; the operator can keep track of the needle during the procedure even if the needle is not in the ultrasound image plane (the entire needle is shown on the display and a guidance bar present on the screen help guide the needle to correct position); it clear shows the trajectory and needle position in real time, so that the surgeon can adapt the position in order to acquire the correct trajectory; it is easier to perform than conventional puncture. Despite the advantages mentioned, the study had an important disadvantage (Table 17.1), which is the fact that none of the 25 study patients had a body mass index greater than 35 kg/m$^2$. In patients with obesity ultrasound images are highly impaired, and the use of fluoroscopy is recommended in such cases. Another disadvantage is that the patient anatomy is shown in 2D [22].

## What is the best method to access the renal collecting system during PCNL?

As we have seen, all the new renal collecting system PCNL puncture techniques discussed here have advantages and disadvantages. All aim to increase the quality of percutaneous puncture execution, so that they can be a credible alternative to the most used techniques. Thus, it becomes necessary to compare new techniques with regard to efficacy, the learning curve required, ionizing radiation utilization, security and morbidity, and the associated costs, in order to understand whether any of them is able to become the standard technique for the future.

For kidney puncture, the renal collecting system puncture technique that used electromagnetic sensors and the technique that used ultrasound with the SonixGPS navigation system had a 100% success rate in the first attempt [18, 19, 21, 22], proving them to be the most effective techniques. This high success rate can be explained by the capacity to define the needle's path and adjustment in real time provided by these two systems. These new techniques allow the operator to know the position of the needle relative to the desired renal calyx to puncture throughout the procedure. The puncture technique that uses an optical system incorporated in the needle had a first-attempt success rate of 73.3% [23]. This lower success rate can be explained by the fact that this technique does not provide an ideal path for the needle. One of the studies of marker-based iPad-assisted puncture showed a success rate on first attempt to approximately 68.4% [15, 16]. In this technique there is no possibility to redirect the needle during puncture, and furthermore the position of the patient must be the same during the preoperative CT and the procedure, and there may be some errors in the path. 3D CT using Uro Dyna-CT for laser-assisted puncture had a success rate at first attempt of approximately 58.3% [20]. Although this technique shows the direction of the needle trajectory and enables adjustment during the procedure, it is markedly impaired by renal movement caused, for example, by the patient breathing. The same technique in an *in vitro* experiment had a success rate on the first try of 80% [15, 16], which may indicate that this technique will need to be enhanced for it to be used regularly.

To a trainee surgeon, the puncture technique using guidance by electromagnetic sensors has a learning curve of 12 cases to reach the level of an expert surgeon [18], much lower than the 60-case learning curve previously reported for PCNL [11], and it is the technique with the best learning curve. Ultrasonography using SonixGPS navigation for renal collecting system puncture is easier to do than conventional techniques, especially for trainee surgeons, since the positioning of the needle can be seen throughout the procedure, unlike conventional methods [21, 22]. The technique that uses an optical system incorporated in the needle does not seem to facilitate percutaneous puncture because it only improves visualization when the needle is already in the collecting system. The model that uses an iPad and markers shows that an expert surgeon takes longer to perform puncturing than a trainee surgeon. This technique is more difficult for the expert surgeon than conventional puncture technique, in contrast to trainee surgeons [15]. The technique using Uro Dyna-CT is more difficult to perform than the others because it requires very specific learning [20].

All the ionizing radiation received during diagnosis, treatment, and follow-up of a patient is cumulative, and may contribute to an increased risk of malignant transformation [28]. Thus, the avoidance of the use of such radiation in PCNL is very important [29]. The puncture of the renal collecting system assisted by electromagnetic sensors allows urologists to dispense with ionizing radiation in an effective way, because the needle and catheter positioned in the desired renal calyx have an electromagnetic sensor which allows the trajectory of the needle to be displayed in 3D and in real time. Thus, the surgeon does not need to view the renal collecting system with fluoroscopy. Puncture of the renal collecting system with an optical system incorporated in the needle does not use ionizing radiation, because its inserted camera system at the needle tip allows visualization of the renal collecting system in real time, and it is not necessary to use fluoroscopy for that. The SonixGPS system also means that ionizing radiation does not need to be used, as it creates the path and relays information about the needle's position in real time. However, these last two techniques use ultrasound, and in complicated cases, such as obesity and anatomical abnormalities, fluoroscopy must be used because ultrasound is compromised in these circumstances. The two other techniques covered here do rely on ionizing radiation: with marker-based iPad-assisted puncture of renal collecting system there is an average dose of radiation exposure of 377.5 μGy per $m^2$ [15, 16] and 3D CT using Uro Dyna-CT for laser-assisted puncture of the renal collecting system has an average dose of 5850 μGy per $m^2$ [20]. Both systems produce a higher radiation dose than conventional fluoroscopy.

Although none of these techniques, when used in humans, have major complications or extensive morbidity associated with them, the small number of individuals included in the studies limits the definition of complications and morbidity. The technique that uses electromagnetic sensors was conducted in pigs. Thus, it will be necessary to obtain the human test results to better understand if it is associated with an increase or decrease in complications and morbidity.

Only Uro Dyna-CT is associated with a very significant increase in financial cost for the realization of PCNL [20]. The marker-based iPad technique may result in increased costs to the extent that there must be a preoperative CT performed, a procedure that is more expensive than fluoroscopy, in addition to the new equipment required for the actual technique. For the remaining three techniques, each requires new equipment, and so a survey of the costs should be carried out related to the purchase of this equipment.

The puncture technique that uses electromagnetic sensors seems to be have the most advantages over the other methods covered in this chapter, but there are currently no human studies reported in the literature.

## Conclusion

Even today, fluoroscopy and ultrasound are still the preferred techniques for performing access to the renal collecting system in PCNL. However, these methods have a steep learning curve and are a source of many complications associated with the procedure. New access methods and technologies have been developed in order to overcome the limitations of the traditional methods. Nevertheless, in the future new human studies will be required to check the efficacy and safety of these new techniques.

### Introduction

Stone clearance and improved patient outcomes during percutaneous nephrolithotomy (PCNL) are largely dependent on the appropriate selection of the access to the kidney. While standard PCNL is often performed through a subcostal lower calyceal approach, upper calyceal access through a supracostal approach can be ideal for many clinical situations. Traditionally, concerns for increased potential perioperative complications, particularly intrathoracic ones, have limited utilization of supracostal access [1]. However, with a good understanding of the anatomy surrounding the upper pole of the kidney and attention to a few technical considerations during the procedure, upper calyceal access through a supracostal approach can be performed safely and efficiently. In this chapter, we describe our surgical technique for upper calyceal access during PCNL and review the outcomes of this approach in the literature.

### Indications and patient selection

During upper calyceal approaches, supracostal access is performed along the long axis of the kidney. This allows for direct entry to the upper calyx and optimal visualization of the renal pelvis, ureteropelvic junction (UPJ), and upper ureter [1]. The performance of rigid nephroscopy in the direction of the long axis of the kidney minimizes the torque requirement on the kidney and results in decreased bleeding and improved clearance rates [2]. In certain circumstances, a laterally situated intercostal tract can be placed between the tips of the 11th and 12th ribs, or an infracostal approach may be used to access the upper pole (Figure 18.1). While the risk of pleural injury may be less with these techniques as compared to the more superior supracostal puncture, the benefits in visualization outside the upper pole is limited with rigid instruments and may require increased reliance on flexible endoscopy [3].

Supracostal upper calyceal access can be advantageous in several clinical situations (Table 18.1). Upper pole access can be optimal for large upper pole stones (Figure 18.2) or for complete staghorn renal calculi (Figure 18.3). Direct access to the UPJ and proximal ureter may be beneficial for treatment of large or impacted proximal ureteral calculi, particularly with concomitant renal pelvic stones, or need for antegrade endopyelotomy during UPJ obstruction management. Similarly, stones in more complicated renal systems, such as an upper pole calyceal diverticulum, or complex lower pole configurations may be more amenable to an upper calyx approach. In situations with superior kidneys located above the ribs, middle or even lower calyceal access may require a supracostal approach. Conversely, in a few patients, upper calyx puncture may be possible via a subcostal route, depending on the renal anatomy. For example, due to its incomplete ascent, horseshoe kidneys are best accessed in the upper pole [3]. However, this can usually be performed from a subcostal approach.

### Anatomic considerations

A general knowledge of the anatomy of the upper pole of the kidney in relation to the surrounding structures is necessary to minimize complications during supracostal access to the upper calyx. The intercostal nerve and vessels

are located along the inferior portion of each respective rib. Puncture sites are directed to the middle portion of the intercostal space to avoid injury to the intercostal artery and development of a hemothorax. In most situations, lateral posterior renal calyces are targeted during percutaneous access to avoid the major branches of the renal artery. Posterior calyces generally traverse Brödel's bloodless line, the avascular renal plane between the anterior and posterior divisions of the renal artery. Additionally, posterior calyces offer the shortest access path to the collecting system [3]. Needle punctures should be directed along the axis of the renal calyx through the center of the renal papilla to avoid infundibular or renal pelvic puncture. Injury to interlobar arteries has been noted in up to 67.6% of kidneys following upper pole infundibular puncture and to retropelvic vessels in 33% following direct renal pelvic puncture [4].

The concern for intrathoracic injury following upper calyceal access is secondary to the close relationship of the upper kidney to the lungs and pleura. The upper portions of both kidneys are located anterior to the posterior portion of the 11th and 12th ribs. A review of 90 normal supine intravenous urograms during full expiration noted that 85% of upper renal calyces are located above the 12th rib [5]. In the prone position, further cephalad movement of the kidney occurs in 80% of patients [6]. Despite controlled maximal expiration, this cephalad movement results in an estimated likelihood of lung injury following supracostal access of 29% on the right side and 14% on the left [7]. The posterior diaphragm arises from the distal ends of the 11th and 12th ribs, the tip of the L1 transverse process, and the anterior aspect of the upper lumbar vertebral body [8]. During full inspiration, the posteroinferior margin of the lung expands to

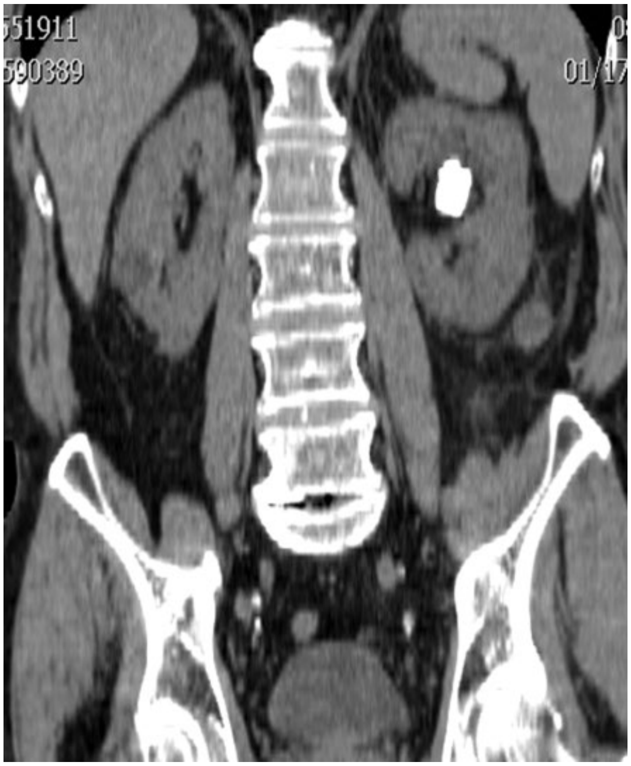

**Figure 18.2** Coronal CT imaging shows a large upper calyceal stone.

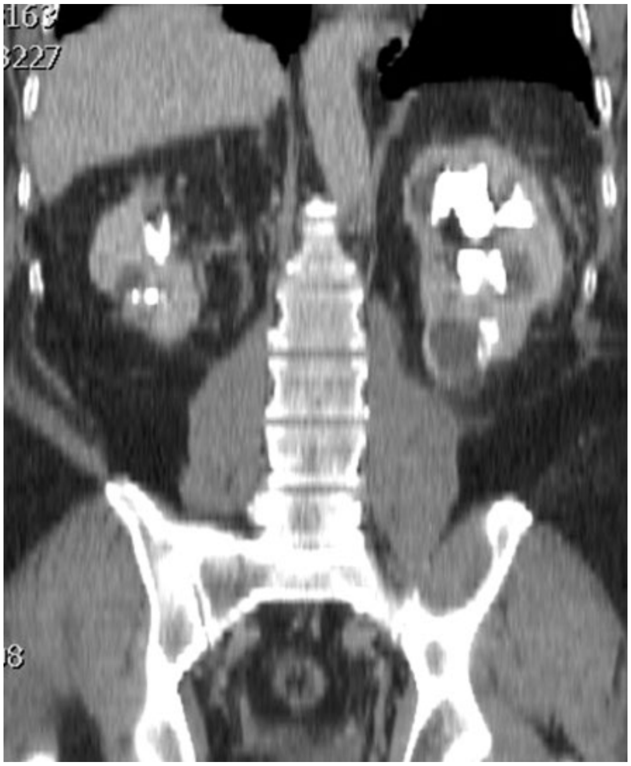

**Figure 18.3** Coronal CT imaging shows a complete staghorn renal calculus.

fill the posterior costophrenic recess. During expiration, the lung retracts and the pleura ascends cranially and laterally on the ribs [9]. The lower limit of the posterior parietal pleura crosses the 12th rib obliquely near the lateral border of the erector spinae muscles. In the midscapular line, the visceral pleura has a similar relationship at the 10th rib [10]. The initial needle puncture for a supra-12th rib access is advocated at maximal expiration and lateral to the erector spinae muscles in the 11th and 12th interspace to avoid lung and pleural injury. Supra-11th rib access can be performed in a similar fashion between the 10th and 11th rib interspace [11].

## Surgical technique

Our percutaneous approach for upper calyceal access is similar to that used for the lower pole. At the onset of the procedure, the patient is placed in the dorsal lithotomy position. Using rigid cystoscopy, we place a 5 Fr open-ended ureteral catheter to allow opacification of the renal collecting system. After subsequent placement of a Foley catheter, the patient is placed in the prone swimmer's position. A chest roll is placed horizontally to facilitate ventilation, with the neck maintained in a neutral position. An additional roll is used to slightly elevate the side of interest in order to align the posterior calyces in a more vertical position. The ipsilateral upper extremity is placed at 90° flexion, while the contralateral arm is positioned parallel to the patient. Particular attention is given to properly pad all pressure points and secure the patient to the table. Using biplanar fluoroscopy, we perform either the bullseye or triangulation technique for percutaneous access. The bullseye technique is described in Chapter 12 in this volume and here we will detail our supracostal approach using the triangulation technique (see Video 18.1).

### Triangulation technique

For upper calyceal access, we generally prefer a puncture site within the 11th and 12th intercostal space, just lateral to the erector spinae muscles. A supra-11th rib puncture is avoided when possible. Following identification of the targeted upper pole calyx under fluoroscopy, the triangulation technique is started with an 18G diamond-tipped access needle puncture in the inferior border of the 11th rib at the skin (Figure 18.4). The needle is angled acutely so that it enters at the center of the intercostal space, thus avoiding the intercostal nerve and vessels of the 11th rib. Biplanar fluoroscopy is performed using the C-arm in two positions, anteroposterior and

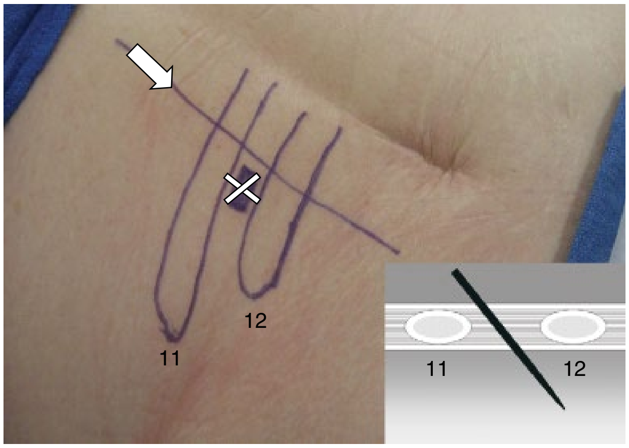

Figure 18.4 Initial puncture for a supra-12th rib approach is lateral to the erector spinae muscles (arrow) at the inferior border of the 11th rib angled towards the middle of the intercostal space (X).

oblique. The anteroposterior view is along the plane parallel to the line of puncture. When the C-arm is in the anteroposterior position, adjustments to the needle position are made in the mediolateral (left–right) direction (Figure 18.5). The oblique view is obtained by rotating the C-arm through 30°. When the C-arm is positioned obliquely, adjustments to the needle position are made in the cranial–caudal (up–down) orientation with care not to drift into the mediolateral position (Figure 18.6). Ventilation is suspended in full expiration as the access needle is advanced towards the desired calyx. The C-arm is maintained in the oblique position in order to gauge the depth of puncture. After initial advancement, the C-arm is rotated back to the AP view to confirm the mediolateral orientation before continuing needle movement in the oblique view. Simultaneous retrograde instillation of contrast via the open-ended catheter allows for collecting system opacification and identification.

After entry into the renal calyx, aspiration of fluid is performed to confirm the needle position in the collecting system. A 0.035 inch hydrophilic nitinol core glidewire is advanced through the access needle and

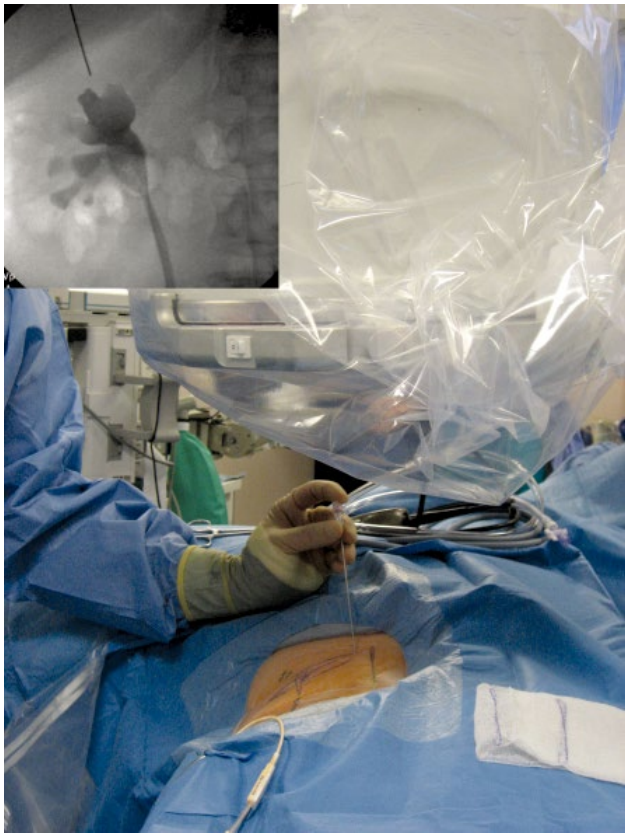

Figure 18.5 Using the triangulation technique for supracostal percutaneous renal access, adjustments to the needle position are made in the mediolateral (left–right) direction when the C-arm is in the anteroposterior position (along the plane parallel to the line of puncture).

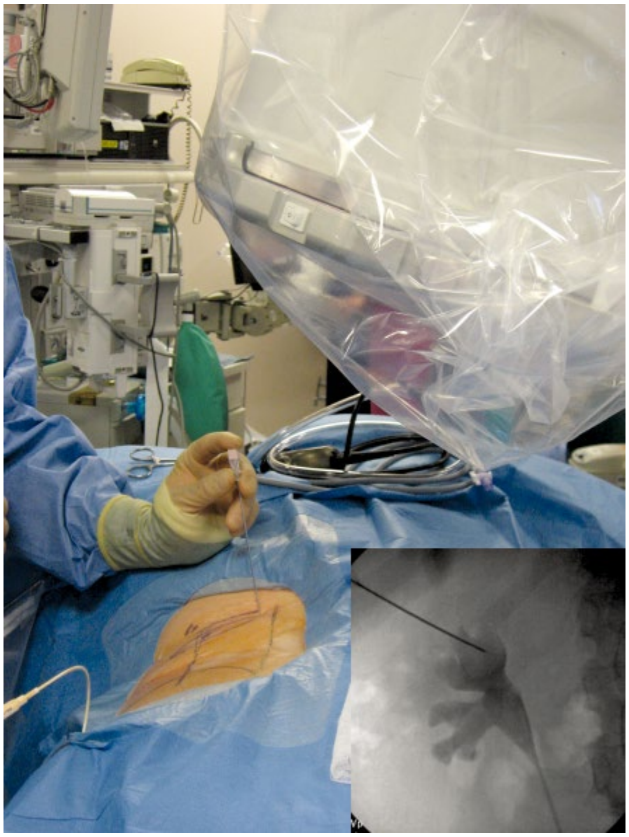

Figure 18.6 Using the triangulation technique for percutaneous renal access, adjustments to the needle position are made in the cranial–caudal (up–down) direction when the C-arm is in the oblique position (rotating the C-arm 30°).

manipulated down the ureter if possible. If entry to the ureter is prohibited, the wire is coiled in the renal pelvis or in the calyx that is accessible and furthest away from the calyx of puncture. An 8 Fr fascial dilator and subsequently a 5 Fr Cobra-tipped angiographic catheter are sequentially passed over the glidewire in order to facilitate wire positioning in the ureter. The glidewire is next exchanged for an Amplatz super-stiff wire. A second standard guidewire is placed as a safety wire into the ureter and secured to the drape following placement of an 8/10 Fr coaxial dilator over the super-stiff wire. A NephroMax balloon is advanced over the super-stiff wire until the radiopaque marker is noted just inside the collecting system. Following balloon inflation to 14–20 atm, the 30 Fr Amplatz sheath is advanced over the balloon into the collecting system and standard stone treatment is performed. Some patients, such as those with complete staghorn calculi, may require additional access into a different calyx following initial percutaneous tract placement in the upper calyx. In this situation, the Amplatz sheath is left in the upper pole while working through the second access tract in order to prevent excessive extravasation from the upper pole calyx into the pleural cavity.

At the conclusion of the procedure, fluoroscopy is performed over the ipsilateral chest and lung fields to exclude the presence of hydrothorax. In the operating room, a pigtail catheter is inserted into the chest under fluoroscopic guidance in patients noted to have significant hydrothorax or pleural effusion. Patients who are symptomatic or for whom there is concern for a hydrothorax in the postoperative period are followed with an upright chest X-ray in the recovery room and monitoring of clinical respiratory vital signs. In the postoperative period, patients with symptomatic fluid collections are managed by tube thoracostomy. On the first postoperative day, a stone-protocol computed tomography (CT) scan, which includes the lung bases, is performed in all patients to evaluate for residual stones.

### Alternative technique

To avoid supracostal puncture, some authors have advocated a renal displacement technique. The initial placement of a sheath, dilator, or externalized through-and-through wire is performed via an interpolar or lower pole renal access in order to allow for torque of the kidney downward. This can be held by an assistant while upper calyx puncture is performed via a subcostal route [12–14]. Additionally, simultaneous fluoroscopy with retrograde flexible ureteroscopy via a ureteral access sheath has been described for endoscopically guided percutaneous access [15]. This modification may aid in rapid and precise percutaneous puncture into the desired upper pole calyx [16].

## Outcomes

Reported stone-free rates following supracostal access PCNL are comparable to infracostal approaches and range between 68 and 90% [17–24] (Table 18.2). The lack of strict criteria defining stone-free status with utilization of multiple imaging modalities may account for some of the variation in reported outcomes. Additional percutaneous access was required up to one-third of the time; this is not surprising given that complete staghorn calculi are one indication for upper pole access. Similarly, ancillary procedures, including second-look PCNL, ureteroscopy and shock-wave lithotripsy, were performed in 3–46% of cases.

## Operative complications

Overall complication rates following supracostal access during PCNL range from 10 to 26% (Table 18.3) [2, 9, 17–24]. Significant hemorrhage requiring blood transfusion or bacteremia and sepsis can occur following any

PCNL procedure. Specific complications in relation to supracostal approaches are described in more detail below. See also Chapters 33–35.

## Pulmonary complications

Intrathoracic complications have been reported in approximately 1–15.3% of cases [2, 9, 17–24]. Supra-11th rib access, in particular, is associated with increased occurrence of pulmonary injuries. In one series, six of 26 (23.1%) supra-11th PCNLs resulted in intrathoracic complications as compared to one of 72 (1.4%) supra-12th rib accesses [2]. Hydrothorax is the most common pleural injury noted secondary to collection of irrigation fluid in the pleural space. In an analysis of isolated upper pole access from the Clinical Research Office of the Endourological Society (CROES) Global study, intercostal access above the 11th rib was associated with a 5.6-times higher rate of hydrothorax than those above the 12th rib [25]. In addition to minimizing access above the 11th rib, the occurrence can be decreased with the judicious use and positioning of the Amplatz sheath to avoid leakage into the pleural space and maintenance of a low-pressure system as well as adequate renal drainage postoperatively [19]. A delayed hydrothorax may occur secondary to urine leakage through the PCNL tract to the pleura, often secondary to the formation of a renopleural fistula. Prolonged fluid accumulation in the setting of a urinary tract infection can manifest as an empyema. A hemothorax may occur following injury to the intercostal vessels during initial needle puncture. The occurrence of an isolated pneumothorax, however, is uncommon [26].

The diagnosis of pulmonary injuries can be made intraoperatively and/or postoperatively. At the conclusion of the PCNL, prone fluoroscopy of the ipsilateral lung fields should be performed in all cases involving supracostal access. A distinct fluid demarcation laterally along the chest wall from the lung or an obscured costophrenic angle warrants further evaluation or intervention if ventilation is difficult. An upright chest X-ray or CT scan can be used to confirm the fluid density at the lung base in less defined cases with high suspicion during the postoperative setting. While under anesthesia, concerning fluid collections may be aspirated during hyperventilation or treated with tube thoracostomy [27]. In the postoperative setting, a period of observation may be warranted with small fluid collections, but aspiration or tube thoracostomy connected to underwater drainage should be utilized in symptomatic patients. An evaluation by a thoracic surgeon for potential thoracotomy or video-assisted thoracoscopic surgery (VATS) may be required for non-improving or infected pulmonary complications. In patients with ureteral stents that show delayed presentation, the effusion may be secondary to stent-related reflux and additionally treated with anticholinergics and maximal bladder decompression. Patients without ureteral stents may have delayed effusions secondary to transient obstruction from small calculi or blood clots, and require ureteral stent and Foley catheter placement [26].

## Other organ injury

Although less common than pulmonary complications, injuries to adjacent organs, including the liver, spleen, and intestines, may occur rarely during upper calyceal access. A retrorenal left colon, occurring in 10% of patients in the prone position, may prohibit access to the 10th or 11th intercostal space with increased risk associated with medial punctures [28]. Additionally, a supra-11th access could puncture the liver in 14% and spleen in 33% of patients, particularly during inspiration [7]. In hemodynamically stable patients, liver injuries can often be managed conservatively with tube drainage and serial monitoring [29]. Moreover, transhepatic PCNL has been reported to be safe if necessary [30]. Splenic injuries, however, are associated with increased bleeding and may require immediate exploration and splenectomy [31]. Preoperative CT imaging to determine the relationship of adjacent structures, as well as evaluation under fluoroscopy in multiple planes intraoperatively prior to needle placement are important methods to minimize injury to other organs [32]. When possible, preoperative imaging should be obtained in the same orientation as the planned surgical position. On planning CT imaging, evaluation of the kidney, particularly to the upper pole calyx, in relation to adjacent organs may differ between the prone and supine positions [33]. In patients at increased risk for adjacent organ injury on preoperative CT, intraoperative ultrasound in place of or augmenting fluoroscopic guidance may additionally be used to gain the optimal and safe access [34].

## Postoperative pain

While not typically quantified in most studies, supracostal access during PCNL results in increased discomfort as compared to subcostal approaches secondary to traversing of the diaphragm [21]. During needle placement, medial puncture through the paraspinal muscles is associated with increased pain and should be limited if possible [3]. Nephrostomy access should be directed to the middle of the intercostal space. While access at the inferior border of the 11th rib should be avoided to minimize injury to the intercostal nerve and vessels, needle puncture and sheath manipulation along the superior border of the 12th rib may result in increased periosteal irritation and pain [35]. Several recommendations have been made to decrease pain following upper pole access. Intercostal nerve block has been advocated as a method to minimize supracostal tube discomfort [36]. Instead of placing a supracostal tube, a lower pole nephrostomy tube may be placed at the conclusion of the procedure via a second nondilated subcostal puncture and allowing the supracostal puncture site to close [37]. Additionally, downsizing to a small-bore percutaneous catheter at the conclusion of the procedure is associated with reduced postoperative symptoms as compared to large percutaneous catheters [38]. Tubeless supracostal PCNL has been reported with decreased need for postoperative analgesia [19, 39, 40]. Tubeless PCNL should be performed only in cases in which complete stone extraction is a near certainty. Candidates for tubeless approaches should meet strict criteria, including no collecting system perforation or significant bleeding [40]. Tubeless procedures should also be avoided in patients with concerns for magnesium ammonium phosphate stones to minimize any potential spread of infection to the chest.

## Conclusions

Supracostal percutaneous access to the upper pole of the kidney during PCNL is a useful technique when optimal visualization is required for the upper calyx, UPJ, and proximal ureter. Supra-12th rib puncture should be approached lateral to the erector spinae muscles towards the superior portion of the rib during maximal expiration. Supracostal access above the 11th rib should be avoided when possible. Intraoperative fluoroscopy of the lung fields should be performed at the conclusion of the procedure, and a strong suspicion for pulmonary injuries should be maintained in the postoperative period. Patients should be counselled appropriately regarding the potential risks and complications when upper calyceal access is anticipated, particularly with regards to intrathoracic complications. However, with attention given to anatomic considerations, supracostal access to the upper pole can be obtained safely and efficiently to contribute to successful percutaneous renal surgery.

# Percutaneous Nephrolithotomy Access Without Image Guidance

*Arthur D. Smith*

*The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## Introduction

In 1955, Goodwin described the percutaneous placement of a needle nephrostomy for hydronephrosis, opening the door to percutaneous renal access [1]. The rapid dissemination of image-guided techniques in urology and interventional radiology has contributed to the innovation of percutaneous renal procedures. Simple drainage has evolved into percutaneous treatments for stone disease, upper tract and renal cancers, and urinary diversion/drainage, among others. The advancement of endourologic techniques has led urology into the minimally invasive era. This rapid innovation has forced urologists to become proficient in percutaneous renal procedures, offering optimal treatment for the expanding number of pathologies amenable to percutaneous treatment.

## Indications

Percutaneous access has been described using various imaging modalities, including ultrasound and fluoroscopy [2–6]. Fortunately, there are few instances in which access must be achieved blindly. Urologists have largely been dependent upon interventional radiology colleagues for percutaneous drainage, but it is becoming an essential skill as it is the procedure of choice for renal access in the acute setting. The inability to obtain retrograde access or opacify the collecting system in a retrograde fashion may be due to previous cystectomy and urinary diversion, locally invasive prostate cancer, benign prostatic hyperplasia, urinary tract fistulas, alternate primary cancers obstructing the ureters, pelvic lipomatosis, and retroperitoneal fibrosis [7]. Renal insufficiency may preclude the use of intravenous pyelography. On rare occasions, access to various imaging modalities may be unavailable, or proficiency with image-guided percutaneous nephrostomy placement may be lacking.

## Anatomy (see also Chapter 6)

The retroperitoneal location of the kidney allows for relatively safe percutaneous access via a posterior approach. Nephrostomy placement without image guidance is completed utilizing anatomic landmarks, assuming normal renal anatomy. A thorough understanding of renal anatomy and relations is essential to avoid complications and gain access to the collecting system [8].

The kidney is a mobile organ and its position can vary depending on patient position and phase of respiration. With respiratory excursion, the kidneys descend on average 4–5 cm, reaching as far as the iliac crest. Generally, the right kidney lies 1–2 cm lower than the left due to its position below the liver. The pleural reflection is posterior to the upper third of both kidneys and needle placement above the 12th rib places patients at additional risk for pneumothorax. The renal hila are directed ventromedially and are approximately 5 cm lateral from the margin for the spinous process of the L1 vertebra. The right kidney is intimately associated with the liver anteriorly and laterally, the colon anteriorly, and the duodenum and vena cava anteriorly and medially. The left kidney is intimately associated with the spleen laterally, colon anteriorly, and tail of the pancreas and aorta anteriorly and medially. Careful needle placement is crucial for safe nephrostomy placement and to avoid visceral organ injury.

## Bony and muscular relations

The average size of each kidney is approximately 11 cm in length, 6 cm in width, and 3 cm in thickness. They lie between the 12th thoracic (T12) and 3rd lumbar (L3) vertebrae. The 11th and 12th ribs are superficial to the upper pole of the kidneys. The intercostal neurovascular bundle courses inferiorly to the corresponding rib, and should be avoided if possible (Figure 19.1).

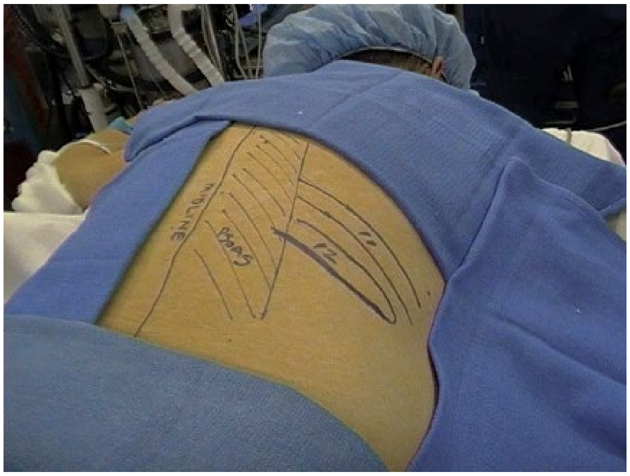

**Figure 19.1** Muscular and bony relations relevant to percutaneous renal access.

The kidneys lie in an oblique plane abutting the psoas which directs its longitudinal axis 30° from the midline, and renders the lower poles more anterior (further from the skin surface) in the prone position. The lumbar notch has been described as a depression that can be palpated, allowing for safe placement of needle puncture [9]. The superior margin consists of the latissimus dorsi and 12th rib, is medially bounded by the sacrospinalis and quadratus lumborum muscles, and laterally by the transversus abdominus and external oblique muscles (Figure 19.2).

## Vascular considerations

The renal artery arises from the aorta at the L1 level, dividing into anterior and posterior branches. The anterior branch divides into three to four segmental arterial branches which supply the anterior and polar regions. The posterior branch gives rise to one posterior segmental renal branch that supplies the posterior surface of the kidney, excluding the polar regions. The segmental arteries give rise to a variable number of interlobar arteries that divide and become the arcuate branches, which subsequently become the interlobular arteries. The interlobular arteries course peripherally in the cortex to supply the afferent arterioles of the glomeruli. Broedel's line represents a watershed zone between the distribution of the anterior and posterior divisions of the renal artery [10]. It allows for percutaneous access through a

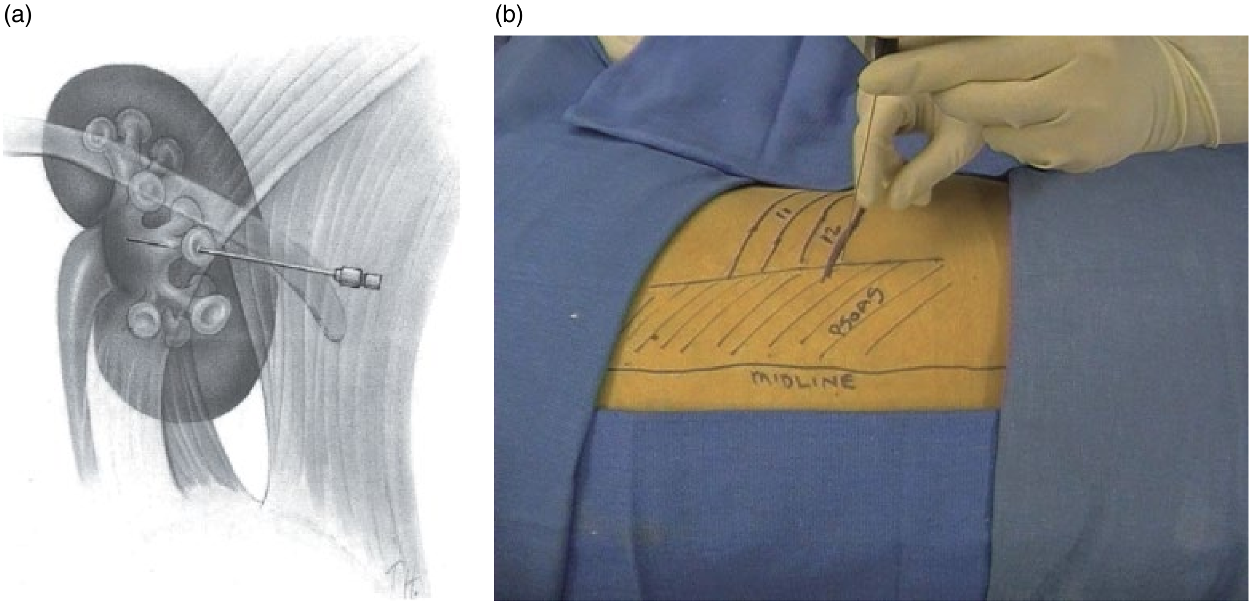

**Figure 19.2** (a) Lumbar notch. The superior margin consists of the latissimus dorsi and 12th rib, is medially bounded by the sacrospinalis and quadratus lumborum muscles, and laterally by the transversus abdominus and external oblique muscles. Figure 19.3 Broedel's avascular zone (shaded).

relatively avascular plane that avoids major arterial branches, potentially avoiding excessive bleeding, pseudoaneurysm formation, and development of arteriovenous malformation (Figure 19.3).

### Calyceal anatomy

Calyceal architecture exhibits a considerable degree of variability. Calyces can be divided into superior, midzone (anterior and posterior), and inferior. Two types of calyceal configurations have been reported, the Broedel and Hodson types [10, 11]. The Broedel configuration describes anterior calyces as being angled medially and posterior calyces more peripherally. The Hodson configuration is in direct opposition with the anterior calyces angled laterally, and the posterior calyces more medially. Kaye and Reinke studied calyceal distribution on computed tomography (CT) imaging and determined that the Broedel type is more commonly seen on the right, and the Hodson type on the left [12].

In clinical practice, emergent nephrostomy decompression without image guidance can most easily be done using a posterolateral approach to access a posterior or lower pole calyx.

## Technique

Prior to proceeding, the patient should be educated on the inherent risks of percutaneous nephrostomy. The lack of image guidance places the patient at slightly greater probability of experiencing an adverse event, as multiple passes may be required to obtain initial access. Preprocedural laboratory values are reviewed, including a coagulation profile, platelet count, and urinalysis. Preoperative broad-spectrum antibiotics are given, and narrowed according to sensitivity profiles when clinically appropriate. General anesthesia is not required in most cases, as use of a local anesthetic and sedation is usually sufficient. The patient is positioned prone with all pressure points padded. The ipsilateral flank is prepped widely, and draped with adequate exposure to facilitate choosing the site of skin puncture.

Initial skin puncture is guided by anatomic landmarks, as discussed previously. The lumbar notch can be palpated, and is an anatomic window that provides the path of least resistance when determining the ideal tract for collecting system access. The 12th rib is identified, and needle entry should be below this point to minimize the risk of pneumothorax and intercostal nerve irritation. After selection of the puncture site, the skin and subcutaneous tissues are infiltrated with local anesthetic.

An 18G sheathed access needle provides stability, can be torqued easily, and does not require exchange to place a suitable working wire. An obstructed, dilated system provides a larger target area to obtain access and can be achieved safely with the convenience of a larger needle. Alternatively, a 22G spinal needle may be used with a 0.018-inch wire for initial entry. A smaller-gauge needle can diminish the risk of clinically significant hemorrhage associated with renal puncture, as well the risk of visceral organ injury [13]. The needle is positioned at the lumbar notch, oriented slightly cephalad, and angled approximately 30° in relation to the vertical axis. The needle is advanced to a depth of 4–5 cm and aspiration can confirm entrance to the collecting system. If initially unsuccessful, negative pressure is applied to the needle while being withdrawn as it may then be slowly pulled back into the collecting system. The needle can be repositioned at the same puncture site and slight modification of angle and depth will allow access to the pelvicalyceal system. Once access is confirmed with aspiration of urine, a hydrophilic atraumatic tipped guidewire is passed gently into the system, to ensure no resistance is encountered. If the initial indication for blind nephrostomy was the inability to opacify the collecting system, an antegrade pyelogram can be performed to retarget an alternate calyx if deemed necessary. In the case of obstruction causing infection, the primary goal is drainage, and which calyx is accessed becomes less relevant. The remaining steps mirror those of the standard percutaneous access. A skin incision is made, and tract dilation is performed 2–4 Fr greater than the size of the desired nephrostomy tube. The nephrostomy tube is passed over the guidewire and deployed along the percutaneous tract in the collecting system.

## Results

The blind percutaneous technique should be reserved for emergent cases in which retrograde access cannot be obtained, opacification of the collecting system is not feasible, or imaging is unavailable. Chien and Bellman reported a 98% success rate in a retrospective review of 40 blind percutaneous renal access procedures, equivalent to that of image-guided access [7]. A single procedure required ultrasound guidance to obtain successful access. No adverse events or complications were reported in their series. The majority (75%) of initial collecting system entries were at the renal pelvis with 17.5% being achieved within the kidney itself, and the remaining being obtained in the upper/lower pole. A comparison of retrograde stent placement versus nephrostomy tube insertion for obstructing calculi with evidence of clinical infection revealed no significant differences in time to clinical improvement or length of stay, although those undergoing percutaneous nephrostomy had increased perceived back pain [14].

## Complications

Percutaneous renal access without image guidance theoretically places patients at increased risk of morbidity. Bleeding complications arise when segmental or interlobar branches are injured and the incidence of severe bleeding ranges from 0 to 2.6% in published series [15]. These can be reduced by ensuring that preoperative coagulation abnormalities are addressed, that 22G spinal needle placement is towards Broedel's avascular plane when possible, and that the number of punctures is minimized [16]. Emergent decompression is largely completed for an obstructed, potentially infected urinary tract. The incidence of septic complications ranges from 1 to 21%, and decreasing manipulation and broad-spectrum antibiotics preoperatively can reduce these events [17, 18]. The risk of pleural transgression increases with intercostal punctures, the rates of pneumothorax and effusion reaching up to 4 and 8%, respectively [19–21]. If intercostal puncture is absolutely necessary, a postoperative chest radiograph should be completed, especially when access is obtained blindly. Bowel perforation is fortunately a rare complication, reported in fewer than 1% of cases, and can be treated conservatively in the majority of cases [22–24]. Visceral organ injury is also rare, yet patients must be informed of this potential complication [25].

## Conclusions

Blind percutaneous renal access can be performed safely, with minimal morbidity when all preoperative factors are addressed. In the appropriate setting, knowledge of this technique can provide urologists with an essential skill set to expedite management and improve patient care.

## Introduction

Since the latter part of the twentieth century, robotic technology has been applied to a number of industrial and manufacturing processes. Due in great part to potential advantages of motion finesse associated with robotic manipulation, recent years have witnessed an increased interest in the introduction of robotics to the healthcare system. Robots were first introduced to the surgical field in the 1980s, and at that time were focused primarily on neurosurgical and orthopedic applications [1]. As interest in robotics expanded into other medical specialties, urologic applications were soon identified. Since that time, robotics has rapidly assumed an integral role in the urologic armamentarium.

The first reported urologic application of robotic technology was described by Davies et al. in 1989, who designed a robot (PROBOT) to perform transurethral resection of the prostate [2–4]. Since that time, a number of targeted research projects have been undertaken to identify and develop applications for robotics within the urologic specialty. In many cases, robot-assisted surgical approaches have become commonly accepted; robot-assisted laparoscopic radical prostatectomy and partial nephrectomy may be the best examples of this.

The suitability of robotics for urologic surgical applications derives from the properties inherent to robotic technology, namely that these devices are versatile, mechanically capable, and programmable. Tasks that are particularly suited to robotic technology are those that require accuracy, reproducibility, fine motor movements, as well as motion that is difficult to perform by hand due to constrained access, such as for laparoscopy, and ergonomic limitations, such as for magnetic resonance imaging (MRI)-guided interventions. To that end, robotic technology can improve on conventional techniques in, for example, securing percutaneous access to the renal collecting system. In this chapter we review the genesis and present applications of robotic systems designed to facilitate percutaneous renal access.

## Goals of robotic percutaneous renal access

Urology has been one of the surgical disciplines at the forefront of the application of robotic technology, and the kidney is rapidly becoming a target organ for this technology. Robot-assisted laparoscopic renal surgery, although only recently described, is becoming a standard surgical approach for renal malignancy and reconstruction. Image-guided percutaneous surgery is likely to be the next generation of renal surgery to benefit from robotic technology [5]. Percutaneous renal surgery encompasses a wide diversity of procedures: nephrostomy tube placement, percutaneous nephrolithotomy (PCNL), percutaneous treatment of transitional cell carcinoma, renal biopsy, renal cyst or abscess drainage, radiofrequency ablation of renal tumors, and percutaneous renal tumor cryoablation. These many procedures are all potential clinical applications for a robot designed to gain renal access percutaneously.

There are a number of practical advantages to robotic assistance for percutaneous renal therapies. For the urologist, one of the most significant challenges of a percutaneous procedure is applying the three-dimensional (3D)

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

renal anatomy to a two-dimensional image representation. In many cases, this anatomic transposition may be confusing. Reliably and safely attaining an optimal point of renal access can require extensive training and experience. Certain clinical situations, such as entry into a nondilated renal collecting system or anatomical variation (e.g. duplex system, malrotation, horseshoe kidney), can be challenging, even for the experienced clinician. There is associated risk of injury to adjacent structures with percutaneous renal access and complex cases may increase this risk. An additional complexity for the urologist, which is not encountered in the orthopedic and neurosurgical fields, is the mobility of the kidney within the retroperitoneum, including its continuous movement with respirations. At many institutions, urologists lack the requisite experience in placing percutaneous access, and such procedures are performed by the interventional radiologist. A lack of participation by the urologist in obtaining percutaneous access for PCNL, for example, may result in the patient undergoing more than one procedure if the access and nephrolithotomy portions of the procedure are performed at times and locations remote from one another. The urologist may also have insights into the manner in which stone removal should be performed, and a lack of such input may result in suboptimal access location. This may translate to longer operative and fluoroscopic times, and subsequently greater risk for complications and higher radiation exposure. Additionally, there are certain complex clinical scenarios where multiple access sites may be necessary, thus requiring further procedures.

Unlike humans, robots are digital devices that are controlled in 3D space. With proper image registration and navigation algorithms, these can be used to address many of the challenges associated with renal access: improved spatial accuracy, programmable, mechanical, and flexible capabilities, and once designed they can be reproducibly used by a surgical novice. With novel technology that allows constant impedance measurements and rotating needle drivers, many of the above-mentioned challenges, such as renal mobility, could possibly be overcome.

The ultimate goals in applying robotic technology to percutaneous access are to increase the ease and decrease the technical challenges of this task, while improving accuracy, efficiency, and reproducibility. Robotic technology holds the potential to provide greater precision than the human hand can, with improved puncture accuracy. Robotic assistance for percutaneous access may ultimately improve surgical performance and decrease complication rates, radiation exposure to patient and providers, and operative times [6].

## Development and evolution of robotic percutaneous renal access systems

Robotic percutaneous renal access systems were first proposed by Potamianos et al., who performed pioneering work in the creation of a passive robot to facilitate needle placement for percutaneous surgery [7–9]. The system was mounted on an operating room table, required fluoroscopic imaging to guide placement, and had five degrees of freedom (DOF). System performance experiments reported at that time described a 1.5 mm targeting accuracy.

In 1996 our urology engineering program, URobotics, was initiated at Johns Hopkins Medicine [10]. This program is dedicated to the development of new technology and gathers both clinical and technical personnel working in close communication to achieve the goal of robotic image-guided surgery. Many of the robotic systems that have been developed over the last 15 years were developed through this program; these systems are discussed below.

### Modified LARS

A prototype system using a modified Laparoscopic Assistant Robotic System (LARS) was introduced in 1997 by Cadeddu et al. [9]. LARS was a modified laparoscopic assistant active robotic system which maintained seven DOF. Each robotic joint was moved by an electric motor, so the access procedure was totally automated. Biplanar fluoroscopic imaging was used to guide the access procedure. The authors described that *in vitro* accuracy was 0.43 mm, and *ex vivo* success with the first attempt was 83%. The authors noted that problems arose with tissue and needle deflection. No comparison to nonrobotic human placement was done with this device, but rather this was a proof-of-concept experiment. This study, despite its limitations, demonstrated that robotic percutaneous access was feasible, although the need for multiple improvements and modifications, such as advanced software, increased DOF, and improved needle design and feedback mechanisms, were identified.

### PAKY

The next generation of robotic systems that was developed for renal indications was termed PAKY (which stood for percutaneous access to the kidney), and also is a product of the URobotics program at Johns Hopkins. PAKY consists of a passive mechanical arm with active translational motion providing needle insertion in a compact and radiolucent module. The device is mounted on an operating room table and can be fitted with a standard trocar needle. An active translational mechanism is used for needle advancement, and fluoroscopy is used to align and monitor needle placement. *In vitro* experiments using PAKY were carried out in 1998 with porcine kidneys and *in vivo* studies were completed in nine human patients [11]. Accuracy was 100% in both *in vitro* and *in vivo* attempts. The mean targeted calyx was 14.7 mm in diameter, and the mean time required to gain access was 8.2 minutes. No complications occurred in any of the trials. These *in vivo* studies demonstrated the robotic system to be steady, safe, and effective, thus serving as a springboard and providing the groundwork for further development of a complete robotic system.

### PAKY-RCM

In 2002 the second-generation PAKY robot, PAKY-RCM (percutaneous access to the kidney with the remote center of motion device), was also introduced by the URobotics program. This is a robot with three active DOF that can remotely align the needle along a selected trajectory pathway under fluoroscopic guidance, minimizing radiation to the surgeon's hands. PAKY is the needle driver and the RCM device is an active robotic arm attached to PAKY that allows the tip of the needle to pivot about a fixed point on the skin. There is a joystick control located on the control box used to advance the needle. Clinical comparison was done using PAKY-RCM versus manual needle placement [12]. There were 23 patients per group and variables measured were number of access attempts, time to successful access, estimated blood loss, and complications. In the robotic group, 87% (20 of 23) of attempts were successful in gaining access. Three patients were converted to manual techniques for various reasons including mechanical failure, and these were successful but took longer than 30 minutes, illustrating the complexity of the access. All manual access attempts were successful. Only single access was needed for all patients, and no major complications occurred in either group. Time to access was not significantly different between the groups ($P = 0.06$), with a mean of 10.4 minutes required for robotic access versus 15.1 minutes needed for manual access. These investigators again demonstrated the robotic access to be both feasible and safe, with acceptable success rates.

### Electrical impedance needle sensor

Entry into the renal collecting system is the requisite endpoint of percutaneous renal access. However, in many cases the urologist has little objective information to confirm this outcome; radiographic imaging can be uncertain and aspiration of urine can be unreliable. To address this clinical problem, the URobotics program designed a "Smart Needle" system, which consists of an access needle fitted with a sensor on the exposed stylet tip that continuously measures electrical impedance (Figure 20.1) [13]. When the collecting system is entered, resistivity drops precipitously. This system was invented to provide objective feedback to the surgeon that access into the renal collecting system has been successfully gained; malpositioning of the needle should be reduced with this device. A series of experiments in which image-guided access to porcine kidneys was performed revealed a significant reduction in resistivity when the needle entered the collecting system in 11 of 16 attempts. The promise of the Smart Needle system rests in its ability to optimize renal access, potentially reducing needle-related complications which may occur during this procedure. This needle, which can provide objective feedback to the surgeon gaining access, may reduce the number of access attempts, increase puncture accuracy, and decrease procedure duration and radiation exposure. The Smart Needle can be used in combination with any of the previously described robotic systems. It should be noted that the Smart Needle was evaluated only in dilated collecting systems and it is unclear if impedance will drop so precipitously in a nondistended system. In addition, urine with altered chemical makeup, such as grossly bloody or purulent urine, may not demonstrate such an objective reduction in resistivity. Further studies are required to better define these potential limitations.

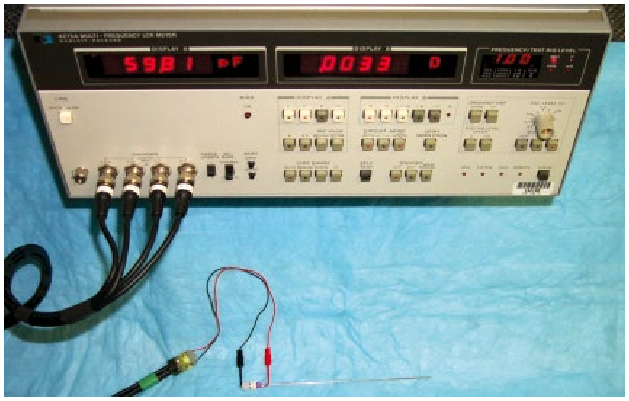

**Figure 20.1** Electrical impedance system for the "Smart Needle."

### AcuBot robot

Needle-based therapies such as thermal ablation and cryoablation are increasingly being utilized for the treatment of renal tumors. Due to the image-guided nature of these procedures, there is interest in the design of computer-assisted navigational systems to increase

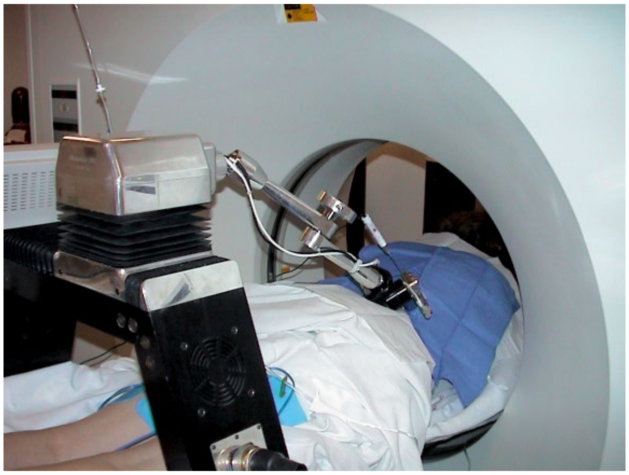

**Figure 20.2** Clinical demonstration of the AcuBot robot.

treatment accuracy. AcuBot is a novel, completely automated, robotic system with six DOF capable of needle placement based on imaging data (Figure 20.2). It has the advantage of changing skin locations for entry and has force sensors. Studies have been conducted in phantom models with computed tomography (CT)-guided imaging to assess and compare accuracy between robotic and manual placement by experienced surgeons and radiologists [14]. Accuracy was 1.2 mm for AcuBot needle placement versus 5.8 mm in manual placement ($P < 0.0001$). The mean time from target acquisition to needle placement was 37 seconds for the AcuBot and 108 seconds for the surgeon ($P = 0.001$). This robotic system has the potential to increase accuracy and decrease operative time and radiation exposure, thus decreasing complications and improving clinical outcome. Further studies in animals and clinical experiments are needed to better characterize this promising technology.

## Revolving needle driver

Most image-guided robots position and orient a needle guide so that the needle is manually placed through the guide [15]. There are advantages in manually inserting the needle through a guide, such as keeping the physician in direct control of the needle, instrument simplicity, and perhaps facilitating regulatory approvals for clinical trials and use. However, this compromise also mediates the full potential benefits of robotic image guidance [16, 17]. The Johns Hopkins URobotics group has recently developed a two-DOF needle driver that, in addition to automated insertion, can spin the needle and perform a set of experiments to assess the influence of needle spinning on the accuracy of needle insertion (see Video 20.1) [18]. Figure 20.3 shows the revolving needle driver device supported by the AcuBot robot. Experiments revealed that spinning is useful for improved targeting and could reduce errors by as much as 70%. Another group at the University of Pittsburgh also focused on the needle driver design for percutaneous kidney access assistance, developing a needle steering system via duty-cycled rotation, although this was only tested *in vitro* [19].

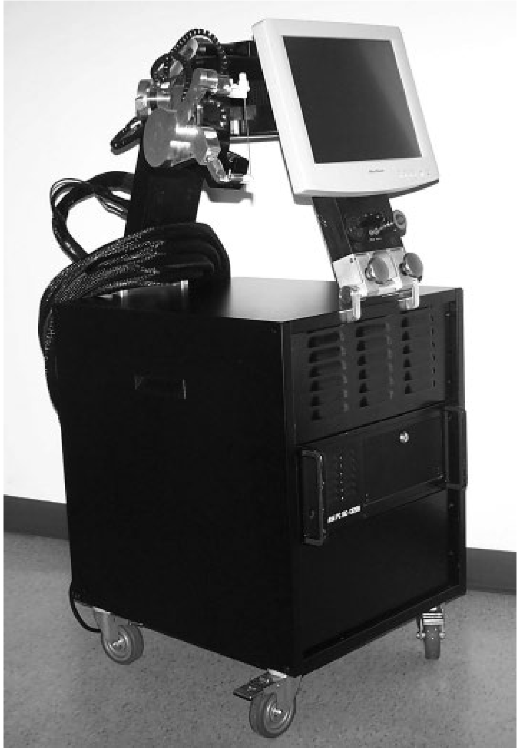

**Figure 20.3** The AcuBot robot with revolving needle driver.

## Mechanical gantry system

While many of these robotic systems are promising, they are also quite expensive. A group from South Africa developed a mechanical gantry system to assist with renal access during PCNL that is more cost-effective [20]. It is also portable and lightweight. It consists of a needle alignment device and a mechanical gantry with six DOF that attaches directly to the operating table. Two images are taken with the C-arm in anteroposterior and oblique positions and subsequently uploaded to a computer software program. The urologist selects the desired access on the screen and the software calculates the needle trajectory. Values are provided for the surgeon to manually adjust the gantry on the table and the needle is then able to be advanced via the needle guide. The system was tested in a phantom model and also porcine kidneys and was accurate and precise.

### Telerobotics and telementoring

Telemedicine has emerged as a promising new field, and provides the ability to disseminate surgical knowledge, particularly complex techniques, to novice surgeons. Both AESOP (a robot for remote manipulation of an endoscopic camera) and PAKY (percutaneous access of the kidney) have been used to study the utility and feasibility of telesurgery and international mentoring [21, 22]. Among the procedures completed were renal biopsy and percutaneous access to perform nephrolithotripsy or place a nephrostomy tube, which was successfully achieved with PAKY [23].

Telesurgery has been the subject of a randomized controlled trial, which compared human versus robotic and telerobotic access to the kidney. Using a validated kidney model, the authors found that in over 304 access procedures, humans were faster than the robot (35 vs. 57 seconds). The robot, however, was more accurate with 88% success of access gained on the first attempt versus 79% success by humans ($P = 0.046$) [24].

## The future

Although much robotic percutaneous access remains investigational, several systems have been tested and applied to clinical situations with human patients. Several of these systems, as described above, have demonstrated great promise in improving safety, accuracy, and clinical outcomes, while decreasing operative times and complication rates. If these goals are achieved, robotic systems have the potential to be both cost-effective as well as medically desirable. Importantly, in the present medical climate, the cost-effectiveness of these systems must be considered, an area of research that remains to be done. However, as time passes and technology continues to be refined, it is anticipated that robots will play ever increasing roles in precise and accurate techniques such as those required for percutaneous access. Additionally, navigation systems for percutaneous renal access, such as iPad-assisted puncture, laser-guided puncture on Dyna-CT, electromagnetic tracking for puncture, and optimal tracking for ultrasound-guided access, continue to develop and may serve to enhance the robotic technology further.

# Dilation of the Nephrostomy Tract

*Peter Alken*

*Department of Urology, University Clinic Mannheim, Mannheim, Germany*

## Introduction

In the past, dilation of the percutaneous nephrolithotomy (PCNL) tract was thought to be essential to extract stones under radiological control [1] or to disintegrate and extract them endoscopically [2]. Today, however, the uses of PCNL tract dilation is decreasing and the options vary between no dilation and one-shot dilation, which is a kind of penetration. No dilation is needed with the microperc PCNL technique performed through a 16 gauge needle sheath [3]. Even a large tract access can be established by "one-shot" without any dilation [4].

All dilation or penetration techniques can be applied safely and with comparable good success and low complication rates when the conditions are ideal and when the surgeon is familiar with the technique and experienced. The classical dilation techniques using serial dilators or balloons [5–7] may continue to exist for a certain time and certain indications parallel to the increasingly popular miniaturized and one-shot PCNL techniques.

## Dilators

The essential difference between balloon dilators and fascial, Amplatz, or Alken dilators and one-shot instruments used in a serial fashion or for one-shot dilation is that the latter all apply forward forces during their advancement while balloon dilation does not.

### Fascial dilators

Fascial dilators made of plastic have a cone-shaped tip and come in different lengths and sizes. Primarily designed for vascular procedures as catheter introducer sets they are available with thin-walled simple sheaths or peel-away sheaths. They are disposable. A reusable metallic 9 Fr dilator and 11 Fr sheath are part of the Alken dilators [8]. For PCNL, fascial dilators are used for preliminary dilation steps before application of the larger dilator systems or together with simple sheaths or peel-away sheaths in a one-shot dilation technique for miniaturized PCNL [9, 10].

### Amplatz dilators

The Amplatz system [6] consists of 12 plastic dilators with conical tips and sheaths of different length and sizes up to 36 Fr. A long 8 Fr dilator fits over a guidewire for a preliminary dilation and to stabilize the guidewire to prevent kinking. The Amplatz system requires repetitive in-and-out movements of the increasing size dilators. As a disposable system it is designed for one-time use only.

### Alken dilators

The Alken dilators [11, 12] were the first purpose-built PCNL instruments and were designed for one-session (pincture–dilation–nephroscopy–stone removal–nephrostomy) PCNL. The system consists of a conical metallic 9 Fr dilator and an 11 Fr metallic sheath which are used for preliminary dilation, introduction of a safety guidewire and atraumatic placement of the 8 Fr hollow guide rod [8]. The eight successive metal dilators up to 30 Fr are advanced over the guide rod, one over the other, up to the required size. The dilators are flat at the dilation end point. Finally a 24 or 26 Fr continuous-flow nephroscope sheath or any Amplatz sheath is advanced over the dilators.

In difficult situations with no passage of the guidewire or the guide rod into the renal pelvis, an 18 Fr nephroscope could be introduced after the third dilation step to inspect the calyx for a safe dilation route into the renal pelvis.

The rigid metallic guide rod (Alken guide) is currently frequently used for one-shot dilations [4, 13–21].

### Balloon dilators

Balloon dilators [7] come with pressure devices to inflate the balloon up to the required diameter of 20 to 30 Fr and sheaths up to 36 Fr and of different length. Preliminary tract dilation with fascial dilators is frequently done. The advantages of balloon dilation are that it is a one-step process, speed (with consequently reduced fluoroscopy time), and the exclusively radial forces during dilation. Balloon dilation is the most expensive technique available.

## Dilation in miniaturized percutaneous nephrolithotomy

The miniaturized PCNL technique was first used in 1997 for the treatment of a child [9]. The tract was dilated to 16 Fr, established with a 15 Fr angiocatheter introducer set with a peel-away sheath, and stones were extracted with a pediatric cystoscope.

Jackman et al. were the first to apply the technique in a series of children and adults [10]; they called it “mini-perc” [22]. They used an 8/10 Fr guidewire introducer set and an 11/13 Fr ureteroscopy sheath set which was cut to the desired working length to introduce ureteroscopes or pediatric cystoscopes. Stones were disintegrated with laser or ultrasonic probes.

Lahme et al. [23] developed the first purposely designed instrument for miniaturized PCNL, called the mini PCNL (MPCNL). They used a single-step dilation with a 14 Fr plastic dilator, 15 Fr and 18 Fr metal sheaths and a 12 Fr nephroscope; the set was designed as a continuous-flow system with outflow via the sheath.

The microperc technique has been designed to allow one-step instrumental access without the need for dilation by puncture only using a 4.85 Fr needle to puncture the collecting system and a 16 gauge needle sheath with an attached three-way connector for irrigation, passage of a telescope, and a laser fiber [3]. Other miniaturized techniques frequently initially use fascial dilators. A recent meta-analysis comparing miniaturized PCNL with standard PCNL showed that dilation was best done with fascial dilators of 13–18 Fr [24]. One study [25] used the minimally invasive PCNL one-shot technique described by Nagele et al. [26] with a metallic one-shot 16 Fr dilator/18 Fr sheath.

Depending on the type of miniaturized instruments, various dilation procedures are used. In a large series on children, serial fascial dilators and 14–16 Fr peel-away sheaths were used [27].

Zeng et al. reduced the fluoroscopy access time by using scaled fascial dilators and sheaths of 18 Fr [28]. With their >10 000 Chinese minimal invasive percutaneous nephrolithotomies Zeng et al. dilated the main tract to 18– 20 Fr and secondary tracts to 14–18 Fr [29]. Bhattu et al. used miniaturized systems from different instrument makers and dilated in single-step or sequential fashion to sheath sizes of 18, 19.5, and 20 Fr [30]. In super-mini percutaneous nephrolithotomy (SMP), tracts are dilated to between 10 and 14 Fr with fascial dilators [31]. Datta et al. dilated with fascial dilators to 7 Fr and 12 Fr and introduced the 13 Fr ultra mini percutaneous nephrolithotomy (UMP) outer sheath [32]. Karakan et al. did a one-shot dilation to 14 Fr using a modified UMP technique [33].

There are various different competing miniaturized PCNL instruments on the market. With all techniques the dilation is less important than what is offered for instrumentation, irrigation, and/or suction within the sheaths and the nephroscopes used.

The small tract of a miniaturized PCNL will forgive a bad puncture much more than a large dilated tract because the trauma is limited size-wise and so puncture-driven complications, such as bleeding or extravasation, will be less frequent and less severe. Complications include (i) vascular lesions of intra- or extraparenchymal vessels, (ii) collecting system lesions by a nontranspapillary access, (iii) rupture of the collecting system in the case of a mismatch between dilation size and collecting system, and (iv) frontal forward perforations.

## One-shot dilation

Establishment of a large tract by “one-shot” access was first used by Frattini in 1998. After puncture of the collecting system and guidewire placement “a single 25 F or 30 F Amplatz dilator was pulled in on the Alken guide or on the 8 F first polyurethane dilator of the Amplatz set. This single passage allowed the insertion of the 34 F working sheath. … Each procedure was performed by a surgeon with great experience in the field of endourology” [4].

Successfully applied for large tract diameters, the one-shot technique can of course also be applied independent of size in all miniaturized PCNL procedures. Previous open surgery on the same kidney had no influence on the good success rate of one-shot dilation [34]. In children, one-shot dilation compared favorably with the Alken technique [17].

A one-shot principle for all sizes is made available by the minimally invasive PCNL (MIP) instruments of Karl

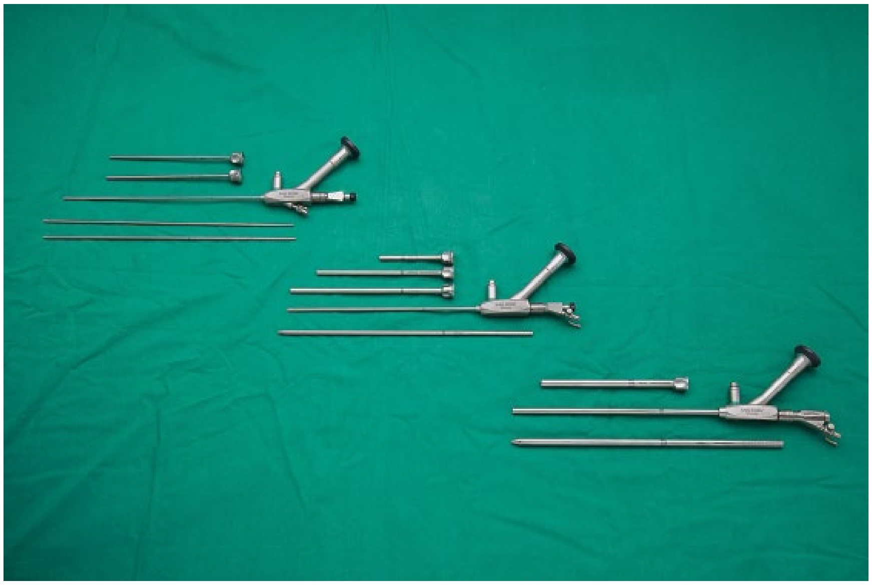

**Figure 21.1** Minimally invasive percutaneous nephrolithotomy dilators, sheaths, and nephroscopes. *Source*: Karl Storz Endoscopy-America, Inc., 2017. Reproduced with permission of Karl Storz GmbH.

Storz, which come in seven dilators sizes between 8,5 and 26 Fr with matching operating sheaths between 8.5 and 26 Fr (Figure 21.1) [35, 36].

The data in Table 21.1 show that access time and access fluoroscopy time are approximately halved with one-shot procedures.

Two recent meta-analysis comparing the different dilation techniques both principally recommended that one-shot dilation should be offered to most PCNL patients [44, 45]. As frequently stated in surgical literature, one additional remark was: "Nonetheless, a large number of multicenter randomized controlled trials of high quality are still required to explore the differences among OSD [one-shot dilation], MTD [metallic telescoping dilation], BD [balloon dilation], and AD [Amplatz dilation]" [44].

Li et al. concluded "Urologists could first choose one-shot dilation for tract creation in PCNL. Even if failure occurs, it is easy to shift from the one-shot to the standard dilation technique" [45]. I agree, but at the same time in a few cases there might be a procedural step when this strategy leads to irreversible catastrophes because the resistance of the tissue is misinterpreted as invitation to double the forward pushing forces – just as with the old techniques. Many of these problems happen but are unpublished.

## Tract dilation: ideal and special situations

Once the access is established by the puncture, the surgeon is aware of the primary quality of the access: probably good = transpapillary; probably bad = every other route. For the following steps the experienced surgeon will rarely have to change or is audaciously using the less than perfect tract; the unexperienced surgeon has the option to change but will frequently choose not to because he or she does not want to give up the access that has been established. These options, the realized or neglected need to do an alternate/better puncture to improve access quality is rarely described or even discussed in relevant publications. Bleeding during PCNL signals a bad puncture or a traumatic intrarenal instrumentation. The contribution of dilation to blood loss is mainly only secondary to widening the needle tract and increasing the trauma of the wrong puncture. Thus comparing transfusion or extravasation rates of different dilation techniques only transfers other details of the whole procedure to the dilation step. This also explains some of the reported variety seen in the literature [46, 47] (Table 21.1). The Clinical Research Office of the Endourological Society (CROES) publications on dilation did not differentiate between Amplatz and Alken dilators and had to do extensive subgroup analysis to try to differentiate between causal and casual relations [46, 47].

The first PCNL step after puncture is the positioning of a guidewire for the subsequent dilation. This is usually possible independent of the access quality. The passage of the guidewire gives first information on the tract quality: it varies between down the ureter "through and through" to outside the urethral meatus and just to the stone. These are first messages on access safety and access perfection.

The puncture is straight but within the collecting system, anatomy and stone shape may require a curved tract. Preliminary dilation with small-diameter fascial dilators will inform the surgeon through any resistance

**Table 21.1** Overview of published dilation procedures, tract sizes, transfusion rates, fluoroscopy, and access times.

RCT, randomized controlled trial.

felt about tract curves that do not become apparent in the anteroposterior fluoroscopy projection.

The tract diameter is negligible outside the kidney, but becomes important within the parenchyma depending on the structures traversed. Within the collecting system it should match the space offered by the collecting system and available between stone and collecting system. The smaller the tract size, the more it will forgive a bad access or unfavorable intrarenal conditions.

### Ideal situation

In the ideal situation all dilation techniques are equally effective and safe: the puncture is transpapillary; its direction exactly matches the long axis of the access calyx; the tract leads through a wide calyx straight into a capacious renal pelvis; the tip of whatever dilator used is well within the renal pelvis; and the collecting system is a significant part of the tract, adding safety space for movements. Only the parenchyma is dilated in an avascular area.

### Less than ideal situations

Less than ideal is a small access calyx or a diverticulum with a caught guidewire because of an angulation between puncture path tract and calyceal axis, or because of a stone blocking the calyceal neck. The risk of losing the tract is increased. Dilators with cone-shaped ends, such as balloons and Amplatz dilators, may create a problem when their straight part is not within the collecting system. With this kind of "short" dilation, advancing the sheath may catch and cut tissue between sheath and dilator. Visual advancement with help of the scope is equally traumatic. Boston Scientific has realized this problem and reacted by producing short-shoulder balloons to allow for dilation within a small space.

The tips of all Alken dilators are in one line when completely advanced, and this design proved to be advantageous in these tricky cases compared to balloon dilators, with access failure rates of 0% and 38%, respectively [48]. Another option is preliminary dilation with a 9/11 Fr dilator/sheath and percutaneous inspection with a rigid ureteroscope to find a proper route for the guidewire or a space between stone and calyceal wall for further dilation [49–51]. A visual dilator, such as an optical trocar in laparoscopy, could be advantageous in these situations [52].

Narrow calyceal necks with nonpliable walls or – even worse – an almost nonexistent simple or bifid renal pelvis are bad candidates for any form of dilation to a standard size as a disproportional diameter of the dilator will cause tissue disruption, extravasation, and subsequent scarring. In these cases the diameter of the different sections of the collecting system dictate the tract size or even the type of procedure. A small-diameter access with flexible ureteroscopy or miniaturized PCNL may be preferable to standard PCNL.

A completely stone-filled calyx is the impossible situation. The needle tip is felt touching the stone but neither dye nor a guidewire enters the calyx. "No PCNL can be performed" [53]. Dilation with flat-tipped telescope metallic dilators directly on that area, while strictly maintaining direction and position, has been done successfully. The nephroscope sheath is introduced and the thin tissue layer is removed with ultrasound lithotrity until the stone becomes visible and access is gained into the stone and the collecting system [54].

## Dilation procedure

Dilation is usually controlled by fluoroscopy but success with sonographic control has been described since 2008 [55]. If the surgeon is familiar with sonography, puncture and dilation with all techniques and even one-shot can successfully be done under pure ultrasound control [18] with few failures (2.8%), even in obese patients [18]. The technique was successfully applied in children to establish a 30 Fr tract in one shot [20]. Preliminary endoscopy through a 16 Fr plastic sheath with a ureteroscope helped to find the right way in the largest series done under ultrasound control [49].

All forward-advancing movements with any dilator or sheath should principally be done with one hand, in a twisting bidirectional rotation with approximately 70–80% of the force turning the dilator and 20–30% pushing it forward. This is surprisingly easier than a predominant forward movement. The force should primarily come from the fingers and the wrist. To prevent forward perforation the pushing hand should always be ready to stop the forward movement immediately; the other hand controls the guidewire or guide rod. Frequent short imaging controls with fluoroscopy or sonography are advisable.

It is only in case of strong tissue resistance outside the kidney that both hands may be used to advance the dilator; again both hands should be able stop the advancing movements within fractions of a second. To prevent a sudden jerky forward movement and perforation the surgeon's arms should be bent at the elbows and drawn to the surgeon's flank. The force does not come from the surgeon's body leant against the dilators but from the arms. If the resistance within the kidney is due to a narrow, scarred collecting system, the dilation process should be abandoned and a different technique of stone removal used. The telescopic dilators may catch tiny pieces of tissue material hindering the twisting movement. Pulling out the last two dilators, cleaning and reintroducing them may help. If using a guide rod (Alken guide) for telescoping or one-shot dilation, its tip should be in a position with as much safety space ahead to the pelvic wall as possible, and this position should be repeatedly adjusted if necessary.

## Complications, renal trauma, and renal function

Any discrepancy between forward pushing forces and the rigidity of the guidewire carries the risk of permanent guidewire kinking or passive guidewire retraction. This can jeopardize the access and make a new puncture necessary. Reinforced guidewires, such as the Lunderquist wire or the Alken guide, should therefore be used during dilation.

Alken dilators require precision and a firm and stable grip on the guide rod to prevent inadvertent advancement and forward perforation with the rod or dilators. The Amplatz system requires repetitive in-and-out movements of the increasing size dilators; bleeding from the tract can happen in between the steps. Tissue resistance to the dilation may lead to repeated buckling of the dilators and uncontrolled tract displacements. Having Amplatz dilators in the deep freeze ready for use has been described as a solution.

Guidewire kinking and losing access with balloon dilation are rare compared to serial dilation techniques. Failures to dilate the tract, especially after previous renal surgery, of up to 17% have been described in earlier series, with scarred tissue not being sufficiently expanded [56], but failure was negligible in a more recent series [57].

A cone-shaped end of any dilator leaves space between sheath and dilator. If during sheath advancement the dilator tip is partially or totally outside the collecting system, so-called short dilation, the sheath will catch, cut, and traumatize any tissue around the dilator tip.

Forward perforation of the collecting system is not a problem with balloon dilation itself and only seldom happens during the subsquent advancement of the sheath; forward perforation with rigid instruments should rarely be a problem by imaging control of the process and a judicious use of whatever dilation technique.

Tangential disruption of tract structures such as the collecting system or the invisible blood vessels is more difficult to control because it is not easy to determine if the structure to be dilated is extensible enough to accept the desired tract diameter and direction. With one-shot dilation this problem may be aggravated as neither the slowly expanding balloon nor the increasing resistance during serial dilation signals a problem to the surgeon. The latter problem is reduced with diminishing tract sizes such as in miniaturized PCNL.

Dilation to 24 Fr did not change serum creatinine or glomerular filtration rate (GFR) significantly in uncomplicated cases, and DMSA SPECT scans showed minimal functional losses below 1.8%. Only cases with complications had more significant changes of creatinine, GFR, and DMSA scans up to 2.7% [58]. This is not very different from recent studies on 30 Fr tracts with split renal function assessed by MAG3 renography. Functional losses were insignificant with one tract and only 2.28% with multiple tracts [59]. Balloon Alken or Amplatz dilation showed no different effects on renal function [60].

Tract dilation to different sizes has minimal measurable permanent effects on renal function. Traxer et al. saw no statistical difference in scar formation six weeks after dilation to 30 Fr or to 11 Fr in animal experiments with fractional losses of parenchyma of 0.63% and 0.91%, respectively [61].

The renal trauma caused by balloon and one-shot dilation may be comparable in its acuteness and if identical tract diameters are reached within one step. The brittle renal parenchyma reacts differently in the different dilation techniques to 30 Fr. In animal experiments serial dilation caused small round defects of 6–12 mm diameter, while ballooning caused 2–3 cm rupture-like parenchymal fragmentation. Nevertheless, final scar formation was similar in these and other experimental studies [62]. A recent clinical study comparing the effects of one-shot and serial dilation on scar formation and renal function showed a small but significant reduction of DMSA uptake and new scar formation or scar progression in nearly 50% of the patients with one-stage dilation compared to only 11% after serial dilation [13]. It may be that one-shot dilation has different consequences.

## Alternative devices and techniques

Alternative dilation devices and techniques have been described, such as the visual dilator [52], single-step balloon/sheath combinations [63–65], tract vaporization [66], a coaxial telescopic dilator set attached to the puncture needle [67], and a small Amplatz set for use in children [68].

The above list is incomplete but then most ideas did not make it to the market. To be generally accepted devices must be applicable in both easy and difficult cases, easy to use, safe, and not expensive. At present, one-shot dilation seems to be the winner on these grounds and with respect to cost (e.g. US$50 in Morocco) [16].

The goal of continuously advancing and technically sophisticated puncture techniques is to render successful access independent of the endourologist's experience. When these techniques are perfected in the near future, publications on combined one-step/one-shot access are to be expected. They could then be classified as penetration.

# Part 5 Stone Removal

## 22

## Rigid and Flexible Nephroscopy

*Timothy Y. Tran*[1] *& Mantu Gupta*[2]

[1] *Providence VA Medical Center, Brown University, Providence, RI, USA*
[2] *Icahn School of Medicine at Mount Sinai, New York, NY, USA*

### Introduction

The first reported nephroscopy was performed when Rupel and Brown inserted a rigid cystoscope through a nephrostomy tract to remove stones during open renal surgery in 1941. Fifteen years later, Goodwin obtained the first percutaneous renal access when contrast was injected into the collecting system while attempting to perform a renal arteriogram.

Since that time, the techniques and technology associated with the percutaneous route for intrarenal surgery has grown tremendously [1]. Percutaneous nephrolithotomy (PCNL), first described in the 1980s [2], is now the gold standard for the removal of staghorn renal calculi due to its minimally invasive nature and high stone-free rates [3]. With advances in instrumentation, use of percutaneous access has also expanded to treating renal diseases such as symptomatic renal cysts, stenotic infundibula, excluded calyces, and upper tract transitional cell carcinoma.

Rigid nephroscopes, with their offset lens and straight working channels permitting rigid instrumention, are the most commonly used instruments to clear stones from the collecting system during PCNL because of their durability and efficiency; however, there are times when, due to anatomic constraints, this instrument cannot perform all of the functions needed to render a patient stone free.

This chapter discusses recent advances in rigid nephroscopy and flexible nephroscopy through percutaneous access and covers equipment and techniques that can maximize efficiency and minimize morbidity for various percutaneous renal procedures.

### Indications for nephroscopy

#### Diagnostic indications

With advances in endoscope technology, scope design (including digital imaging), and the use of access sheaths, the diagnostic accuracy of retrograde ureterorenoscopy for upper tract urothelial carcinoma is now 76–98%. Rigid and flexible nephroscopy as purely diagnostic procedures are therefore not routinely performed [4–6]. However, in certain patient populations, for example patients who have had cystectomy and urinary diversion who no longer have readily obtainable reterograde access, the percutaneous route may be the only option for access to the pelvicalyceal system.

#### Therapeutic indications

With the combination of rigid and flexible nephroscopy techniques, percutaneous nephroscopy can be used to treat the following:

- Stone disease: treatment of large or complex/staghorn calculi.
- Obstructed calyces, infundibular stenosis, and calyceal diverticula: access obtained in a “direct” manner in which the percutaneous access is directed at the obstructed area or an “indirect” approach where the obstructed area is accessed via another puncture site.
- Ureteropelvic junction (UPJ) obstruction: antegrade endopyelotomy and/or endopyeloplasty with a balloon cutting device, holmium:YAG laser incision, hook knife, Sachse urethrotome, or endoscopic shears [7].
- Upper tract transitional cell carcinoma (TCC): ablation of tumors with lasers or resection with a cautery system.

This chapter focuses on rigid and flexible nephroscopy for stone disease. Chapters 28, 30, and 31 provide further detail on using antegrade access for calyceal diverticulae, UPJ obstruction, and upper tract TCC, respectively.

### Indications for flexible nephroscopy

The chief indication for flexible nephroscopy is access to calyces with stones or tumors that cannot be reached with the rigid nephroscope.

Achieving stone-free status with a single procedure is an important consideration for both the patient and the provider. From a patient perspective, a second procedure can be very costly in terms of time away from work or quality of life. For the urologist, performing a secondary procedure during the 90-day global period can be unappealing. It is common, however, for a surgeon to encounter a case where a patient cannot be rendered stone free using a single access and a rigid nephroscope. As such, the flexible nephroscopy is an important adjunct to rigid nephroscopy for complete stone clearance.

Flexible nephroscopy has been growing in popularity recently as surgeons have shown its use can avoid the need for an additional access. Williams and Leveillee showed that a combination of flexible and rigid nephroscopy can be successfully used to render patients stone free, even in the face of complex stone disease [8].

Flexible nephroscopy can also be used through a percutaneous access to treat obstructed calyces or a calyceal diverticulum when a rigid nephroscope cannot reach the infundibulum due to its acute angle or tightness (Figure 22.1) [9]. This indirect approach to an obstructed calyx or calyceal diverticulum is becoming more commonly utilized as opposed to a direct approach, wherein the obstructed calyx itself is percutaneously punctured, a tract established, and the stenosis treated directly. The advantage of the indirect approach is that it obviates the need for a separate nephrostomy tract with its attendant morbidity.

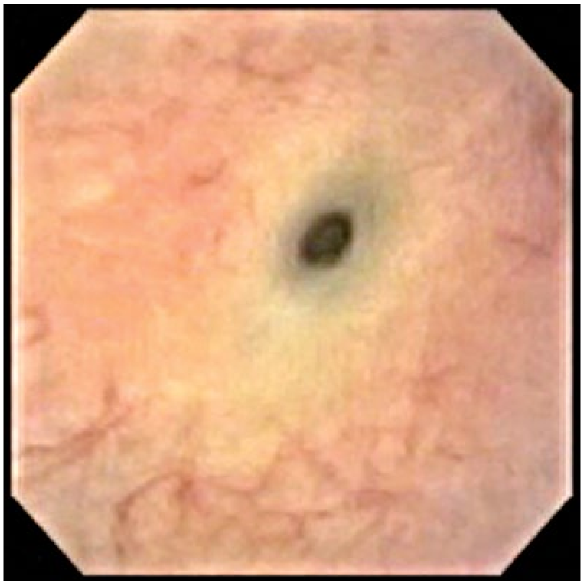

**Figure 22.1** A stenotic infundibulum.

Occasionally, a conventional flexible cystoscope may be too large or too cumbersome to be maneuvered into a calyx. In such instances, use of a flexible ureteroscope to access difficult-to-reach calyces increases the chances of rendering a patient stone free. These are generally 7 or 8 Fr and tend to have better deflection than the flexible cystoscope. Problems are encountered with fiber-optic flexible ureteroscopes because their long length renders them not ergonomically suited for use in the kidney, their relatively flimsy nature makes them torque unstable, and their slender profile and tight distal radius of deflection make them difficult to maneuver in hydronephrotic collecting systems. Use of antegrade ureteroscopy with a flexible ureterosocpe can prove valuable for stone fragments that are located in the distal ureter, since this area usually cannot be directly accessed with a flexible cystoscope because of its distance from the percutaneous site and because of the diameter of the ureter.

The need for flexible nephroscopy during PCNL depends largely on the location of the stone and of the access. Most urologists prefer to obtain access below the 12th rib in order to reduce the risk of pleural injury. In those cases, the rigid nephroscope is usually introduced into the lower pole. The renal pelvis can usually be reached with this access, but reaching upper and mid pole calyces without placing substantial torque on the renal parenchyma is difficult, especially in obese patients or in patients with low-lying kidneys due to hindrance from the iliac crest. It can also be challenging to reach other lower pole calyces from this position and almost impossible to evaluate the proximal ureter with a rigid nephroscope (Figure 22.2). Alternatively, if access is into the upper pole, it can also be difficult to reach the lower pole calyces, especially in patients with narrow intercostal spaces or nonmobile (fixed) kidneys.

## Recent advances in scope technology

Since this volume's last edition, the armamentarium of digital flexible ureteroscopes has expanded. Although the Invisio digital DUR-D flexible ureteroscope (ACMI, Southborough, MA, USA) is no longer available, the Flex-X$^c$ (Karl Storz, Tuttlingen, Germany) and the URF-V (Olympus, Tokyo, Japan) are commonly used. Each scope offers a reasonably narrow tip (8.5 Fr) and 270° deflection in both directions. Additionally, the

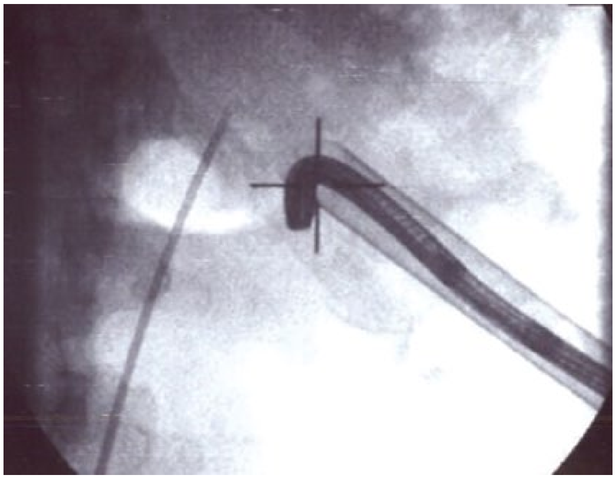

Figure 22.2 Reaching a lower pole calyx with the flexible nephroscope.

URF-V offers narrow band imaging and the Flex-X$^c$ offers Storz professional image enhancement system (SPIES)™ technology (Karl Storz, Tuttlingen, Germany), which can improve detection of upper tract urothelial tumors [10]. Richard Wolf (Vernon Hills, IL, USA) offers the Boa Vision and Cobra Vision digital ureteroscopes, which have similar functionality as the URF-V and Flex-X$^c$.

Recently, the LithoVue™ flexible ureteroscope (Boston Scientific, Marlborough, MA, USA) has been introduced as a new-generation single-use instrument. Dragos et al. demonstrated similar performance in terms of maneuverability, angle deflection, and ability to access calyces during retrograde renoscopy [11]. As an alternative to reusable ureteroscopes, its proposed advantages include high-quality images with each use (as there would be no damage to a new scope) and financial savings on servicing and cleaning costs. Overall, the improved torque stability of digital ureteroscopes in comparison to fiber-optic ureteroscopes allows for improved manuerverability through tight infundibula or hydronephrotic systems.

Similarly, improvements in image-processing technology have yielded benefits for the endoscopic surgeon. The SPIES™ provides a high-definition image with real-time image enhancements useful for nephroscopy [12]. The SPIES CLARA™ feature automatically brightens darkened areas, which eliminates the need for either increasing the light intensity or bringing the scope closer to a darker area. These improvements eliminate the need for maneuvers that may cause glare or result in loss of perspective of the surgical field.

Digital cystoscopes offer similar improvements in visualization compared with their fiber-optic counterparts. However, in contradistinction to digital ureteroscopes, the increased rigidity and girth of these scopes and their more limited deflection can limit their maneuverability and their ability to reach all calyces within the collecting system. As such, oftentimes a fiber-optic cystoscope can be of greater utility for flexible nephroscopy.

Since the publication of the last edition, few changes in rigid nephroscopy and in technology for rigid nephroscopes for standard PCNL have been described. Innovations in scopes for smaller caliber PCNL (i.e. mini-, ultra-mini, and micro-PCNL) are described in Chapter 24.

## Importance of access site (see Video 22.1)

The initial percutaneous access to the kidney influences which calyces can be reached. If a patient has a single stone in an interpolar calyx, it makes sense to access that calyx directly. If there are multiple stones or staghorn calculi, access is usually first obtained in the upper or lower pole, making interpolar access difficult to achieve with a rigid scope. Also, since a rigid scope entering posteriorly faces the anterior calyces, it is more difficult to go from a posterior calyx to another posterior calyx. Some general guidelines for various access sites are given below.

### Posterior upper pole access

If posterior upper pole access is obtained, generally the other more anteriorly located upper pole calyces can be reached with the rigid nephroscope, especially if there is a moderate degree of hydronephrosis. If there is no significant hydronephrosis, or if the access site is close to the infundibulum instead of the peripheral end of the calyx, then it most likely will not be possible to visualize or enter the other upper pole calyces and flexible nephroscopy is necessary. From the upper pole, the rigid nephroscope can be used to enter the anterior lower pole calyces, but entry to the posterior lower pole calyces is challenging (Figure 22.3). Unless there is significant hydronephrosis, the rigid nephroscope cannot enter the interpolar calyces and flexible nephroscopy must be used.

### Interpolar access

As previously mentioned, if posterior interpolar access is obtained, usually the rigid scope cannot access anything other than the renal pelvis and ureter. This access should only be chosen if stones are located in a solitary interpolar calyx and/or the renal pelvis or proximal ureter.

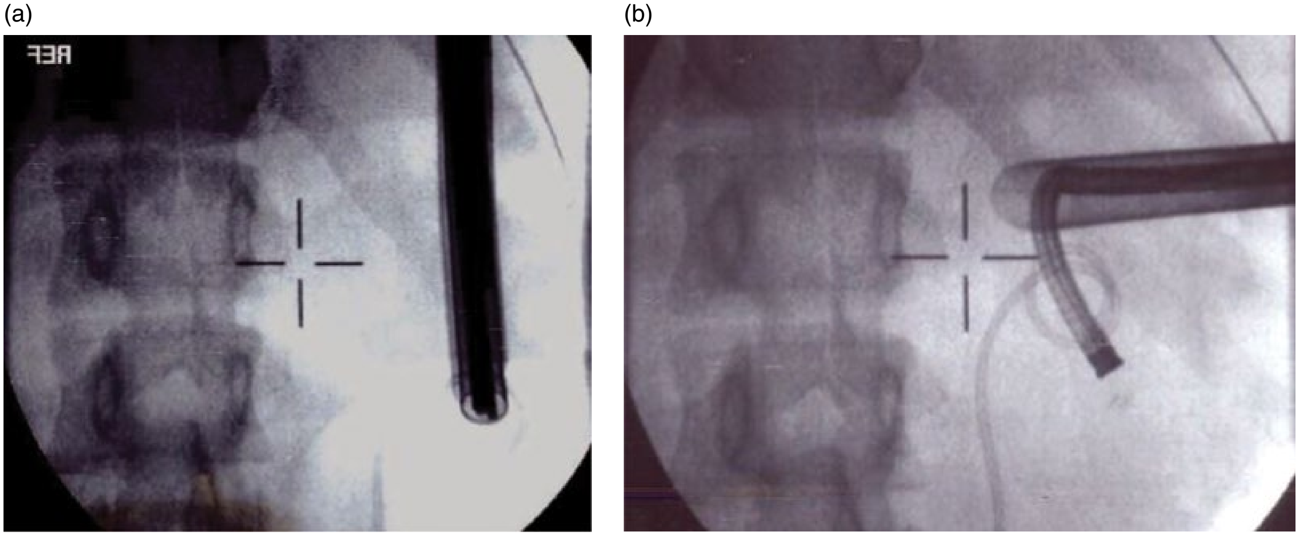

Figure 22.3 (a) Reaching a lower pole calyx with a rigid scope. (b) Reaching a lower pole calyx with a flexible nephroscope.

## Posterior lower pole access

With a posterior lower pole approach, often the other more anteriorly located lower pole calyces can be entered if the access site chosen is more *medial* than usual. To achieve this, instead of rotating the C-arm through the usual 30° toward the surgeon, it is rotated only 20°. This slightly more medial approach, in our experience, does not risk vascular injury and yet provides excellent ability to reach all lower pole calyces. It is particularly useful for partial staghorn calculi that have no upper or mid pole components. From the lower pole, unless there is severe hydronephrosis, the upper and mid pole calyces cannot be reached at all and flexible nephroscopy is necessary to clear them of residual stones (Figure 22.4).

Likewise, the ureter cannot be accessed with rigid scopes or instruments, and flexible scopes are needed. Use of the Accordion™ device (Percsys, Palo Alto, CA, USA), a 15 mm coaxial film-based occlusion device, permits lower pole access for complex stones without fear of stones migrating down the ureter that will then require flexible ureteroscopy at the end of the procedure (Figure 22.5) [13]. Use of this device can ultimately help save time and cost of percutaneous stone procedures.

## Intercostal access

The degree of maneuverability also depends on whether triangulation was used to obtain upper pole access or if an intercostal approach was chosen. Intercostal access will usually allow more maneuverability with less torque on the renal parenchyma, provided that the intercostal space is wide enough. On occasion, the space between ribs is very narrow and the sheath is sandwiched so tightly that maneuverability is significantly hampered.

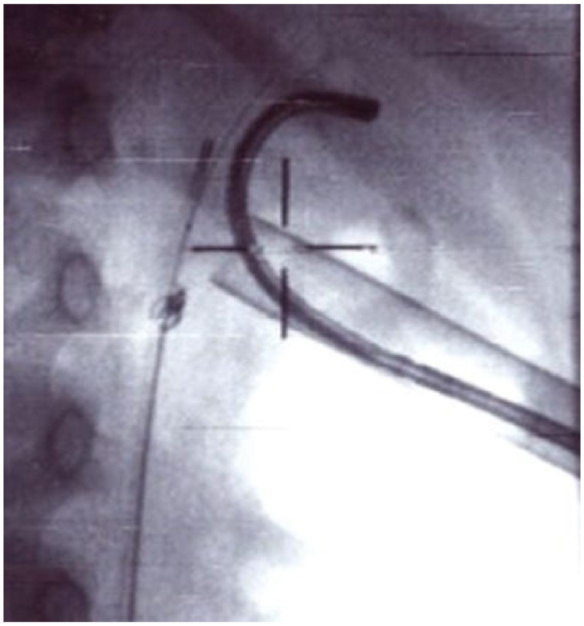

Figure 22.4 Reaching upper calyces with a flexible nephroscope through a lower pole access.

## Preventing ureteral stone migration and obtaining safe percutaneous access

During PCNL the coaxial Accordion™ device can serve several purposes. It is usually placed in the collecting system over a guidewire at the beginning of the case and deployed at the UPJ. Since the lumen of the device accommodates a 0.038-inch guidewire, it is ideal for performing urine sample collection as well as retrograde pyelography. Once it is deployed at the UPJ, it is very effective in preventing stone migration down the ureter, obviating the need for ureteroscopy at the end of PCNL.

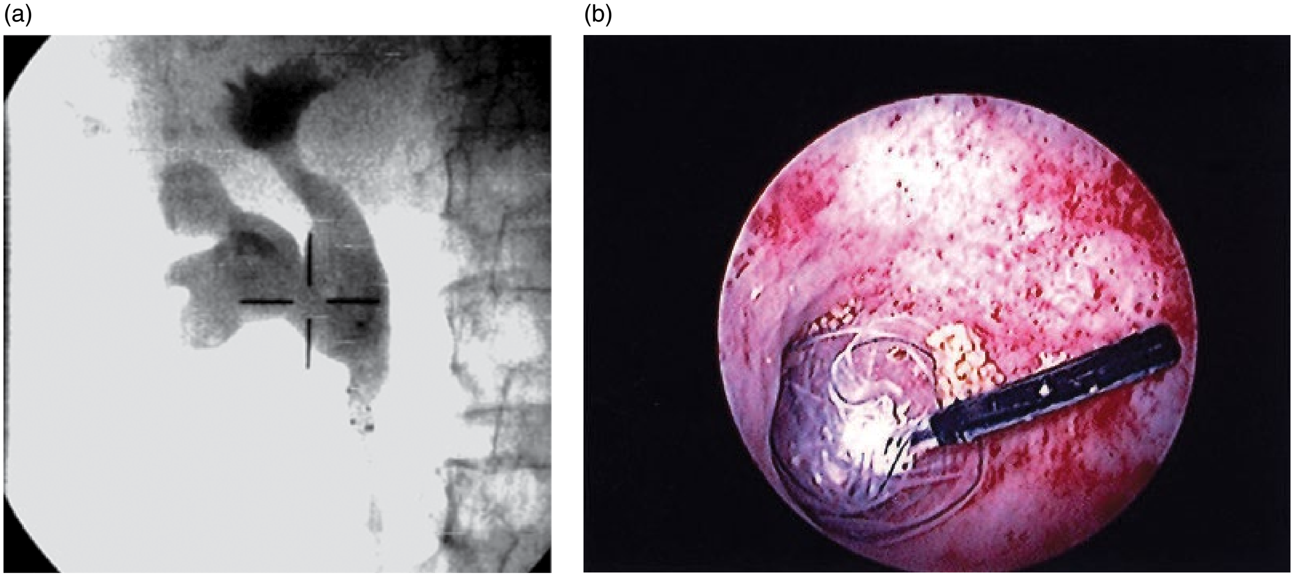

**Figure 22.5** (a) Fluoroscopic image of the Accordion device deployed at the ureteropelvic junction. (b) Accordion device preventing antegrade stone migration.

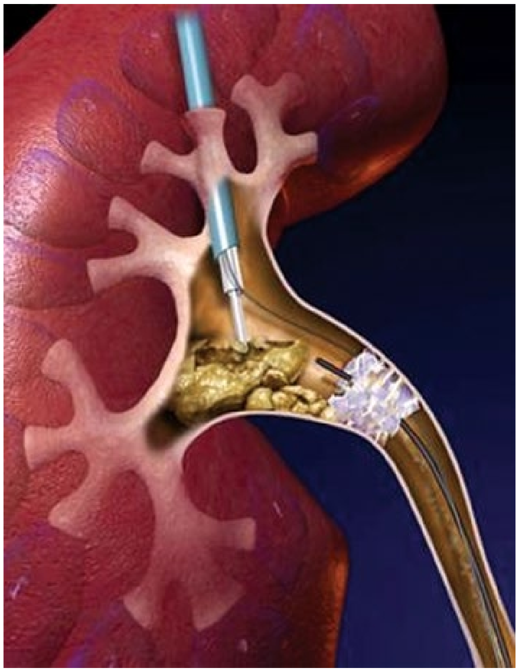

**Figure 22.6** Accordion device deployed at the ureteropelvic junction.

Intercostal renal access during PCNL and other percutaneous renal procedures are associated with an increased incidence of pneumothorax, hydrothorax, or hemothorax postoperatively. The Accordion device can be used to prevent upward migration of the kidney in situations when intercostal access initially appears unavoidable, allowing establishment of a more favorable subcostal renal access (Figures 22.6 and 22.7). Deployment of a coaxial film-based occlusion device at the UPJ can be used to gently hold the kidney in its lower position during ventilation, and in this position percutaneous needle placement can be obtained without the need to go above the ribs. This method provides an effective way to obtain more favorable percutaneous access, limiting the risk of complications associated with intercostal renal access. Visual endoscopic inspection of the UPJ has confirmed the atraumatic nature of this maneuver.

## Stone fragmentation and retrieval

### Rigid nephroscope

The step-by-step processes of obtaining access, dilating the nephrostomy tract, and placing an access sheath are described in detail earlier in this volume. After these steps are completed, the rigid nephroscope is inserted.

Depending upon the nature of the stone burden, retrieval may involve simply grasping the stone fragments and removing them through the sheath. Alternatively, if the stones are too large to pass through the sheath, fragmentation may be required. A variety of lithotripsy devices are used for stone fragmentation during PCNL and are discussed in Chapter 26. In our experience, the combination of selective fragmentation with the StoneBreaker™ Pneumatic Lithotripter (Cook Medical, Spencer, IL, USA) and retrieval with a two-prong atraumatic forceps allows for efficient stone removal with minimal trauma to the urothelium. In addition, use of a

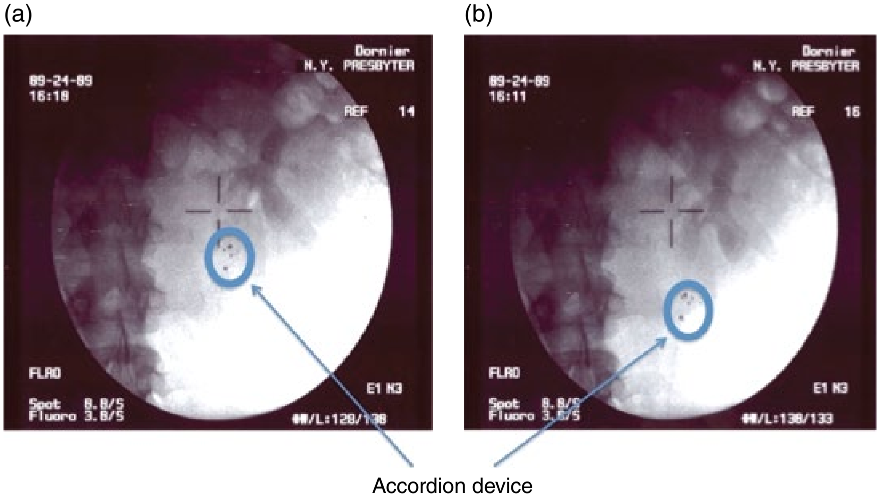

**Figure 22.7** Accordion device preventing upward migration of the kidney to facilitate subcostal upper pole access.

ureteropelvic junction occlusion device, such as the Accordion, is helpful in preventing ureteral migration of stones during this process.

## Flexible nephroscope

Once the affected calyx is reached with the flexible nephroscope or ureteroscope, the size of the stone(s) to be removed must be gauged relative to the width of the infundibulum. If it is likely that the stones can be pulled through the infundibulum intact, a basket or grasper can be used. The NGage® basket (Cook Medical) is particularly useful for efficiently grasping a stone (Figure 22.8). The advantage of this device is that it has an open end and can "cup" a stone that is attached to a papilla or is impacted against the wall. In addition, if the stone is too large to pull through the infundibulum, it can be easily released.

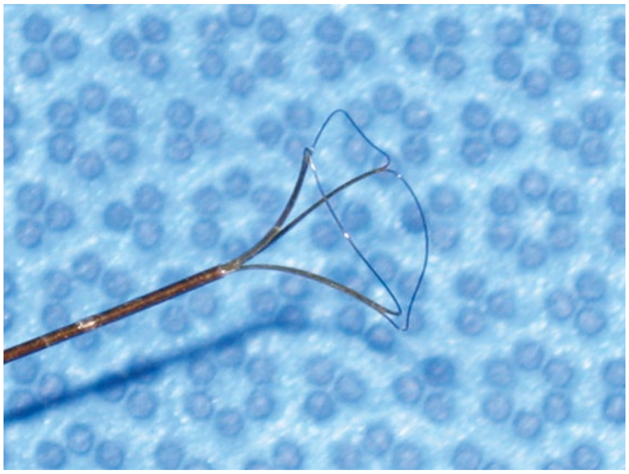

**Figure 22.8** NGage basket.

Baskets are useful for free-floating stones. A basket must be chosen that is sturdy enough to remove the fragments but small enough to allow the scope to deflect. For flexible nephroscopes with their large working channels, 2.4 or 3 Fr nitinol baskets should be used because they are sturdier than smaller profile baskets and can grab larger fragments. For flexible ureteroscopes, 2 Fr or smaller baskets are preferred because they permit better irrigation.

If the stones to be removed are too large, the holmium:YAG laser can be used for lithotripsy. It is important to balance the size of the fiber with the deflection of the scope; a larger fiber will make it more difficult to deflect but will disintegrate the stone faster because of the larger fiber surface area in contact with the stone. Most endourologists generally use a 360 μm fiber through the flexible nephroscope, but a 200 μm fiber through a flexible ureteroscope as it easily fits through all flexible ureteroscopes without significantly affecting deflection or irrigation. The settings to be used depend on the effect desired and the nature of the stone. If the intention is to create miniscule particles that will be left behind for spontaneous passage or flushed out of the calyx and then suctioned (uric acid, phosphate, and struvite compositions are most amenable to this), then low power (i.e. 0.5 J) at a faster frequency (i.e. 10–40 Hz) should be used, and the periphery of the stone should be ablated gradually until the center is reached. The remaining central piece can be retrieved with a grasper or basket. If the stone is very durile (e.g. a calcium oxalate monohydrate or cystine stone), then it should be carved into a few large pieces using high power (1.0 J) and lower frequency (3–5 Hz). The resultant pieces should be removed in piecemeal fashion.

Tiny fragments that are too small to basket are often broken off by the laser. One technique to eliminate these is to irrigate with a 10 ml syringe through the working channel of the flexible scope to flush these fragments out of the calyx. If they are small enough, they can even be aspirated with the syringe. The most effective technique also includes changing the position of the patient to maximize the drainage of these fragments. For example, if the patient is in the prone position and the fragments being flushed are in an anterior calyx, the patient can be rotated to the opposite side so the fragments fall into the renal pelvis. One can also use Trendelenburg and reverse Trendelenburg as necessary to allow stones to enter the renal pelvis. In our experience, fragment migration into the ureter is mitigated by using the Accordion device described above. From the renal pelvis, the fragments can be easily retrieved by the rigid nephroscope using atraumatic peanut forceps with minimal to no irrigation, keeping the patient tilted away from the surgeon to keep the fragments from falling back into the anterior and lateral calyces.

On occasion the Perc NCircle® device (Cook Medical) can be invaluable for retrieving stones from otherwise inaccessible calyces via the rigid scope (Figure 22.9). This unique device is a 5 mm coaxial semirigid instrument with a tipless, large nitinol basket on the distal aspect. Deployment of the basket into a calyx is usually possible as long as the infundibular neck of a calyx can be directly visualized, even if the neck is too small or too peripheral to allow direct access with the scope. Using a combination of direct vision or fluoroscopy, stones can be readily insinuated into the basket and retrieved by pulling them out through the infundibulum. If the neck is too tight to allow stone removal, it is a relatively simple task to open the basket and disengage the stone.

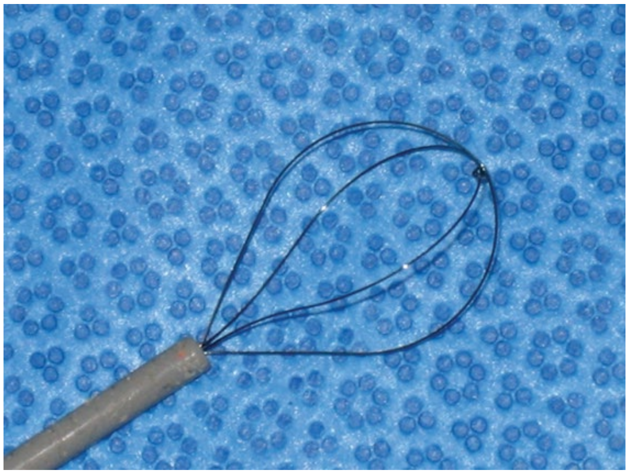

**Figure 22.9** Perc NCircle device.

## Tips and tricks

### Rigid nephroscopy

Although it is preferable that the nephrostomy tract enters directly into the calyx of interest, at times this may not be possible (i.e. calyceal diverticulum or calyx densely filled with stone). In situations where the dilated tract is short of the collecting system, the balloon dilator can be reinserted deeper and re-dilated. Alternatively, if it is known that the tract is directly adjacent to a calyx full of stone, the rigid nephroscope and the atraumatic peanut forceps can be used to carefully probe the surrounding tissue for hard stone. Upon identifying the stone, the mucosa can be gently opened with the forceps and the access sheath advanced to allow direct access to the stone. If, while probing, it is challenging to identify the collecting system, diluted methylene blue can be injected through the retrograde ureteral catheter. This can distend the collecting system with a blue hue and also make entry into a calyx very obvious as there will be a rush of blue fluid that can be followed to the collecting system.

In our experience, we have found that dilation to and use of a 24 Fr access sheath has allowed for several benefits while maintaining the same high stone-free rate associated with standard PCNL. Lipsky et al. reported a significant decrease in blood loss, shortened operative time with decreased hospital length of stay [14]. Additionally, the smaller access diameter results in higher velocity flow through the sheath, which facilitates greater expulsion of stone fragments and can help decrease operating time. This "modified PCNL" has been our technique of choice over the last 5 years due to the aforementioned benefits.

### Flexible nephroscopy

Minimizing the use of contrast with the flexible nephroscope is important as contrast extravasation would render fluoroscopic visualization of residual stones very difficult. In our experience, contrast is used only at the very beginning of the procedure to outline calyceal anatomy and to help guide access, then again at the very end after the nephrostomy tube has been placed.

Visualization is often adequate with a rigid scope because of high volume irrigation, but once the flexible scope is employed, visualization can significantly deteriorate in the presence of bleeding. This is partly due to the optics, but even more to the reduced irrigation with a flexible scope and the inadequate distention of the collecting system. Raising the level of the irrigation fluid or use of pressure bag irrigation can significantly enhance visualization by clearing the field of blood and by distending the collecting system. In addition, advancing the sheath over a particularly troublesome site of bleeding can be of utility to help limit bleeding into the field.

One important technique is the use of fluoroscopy to help guide placement of the flexible nephroscope. If direct visualization is not sufficient to visualize an intended calyx (either because of angulation, a severely hydronephrotic collecting system, or bleeding), brief continuous fluoroscopy can be used to gently maneuver the scope toward a stone in a peripheral calyx. This is generally a very safe maneuver because the blunt end of a flexible nephroscope is wide and atraumatic. Also, since the scope is flexible, perforation is unlikely.

If the opening to a calyx can be visualized with a rigid scope, but it is difficult to find with a flexible scope because of bleeding or incomplete distention of the collecting system, a guidewire can be placed into the intended calyx via the rigid scope. The best wire to use for this purpose is a short, heavy-duty J wire (Cook Medical). The short J wire with the "J" hooked distal tip is atraumatic and therefore is less likely to perforate the calyx or to be dislodged while transitioning from the rigid scope to a flexible one. The flexible scope is not placed over the wire, as this almost always dislodges the wire from the calyx; instead, the flexible scope is advanced alongside the wire and follows it to the calyx of interest. In this manner, the working port of the flexible scope is free for the placement of instruments. In addition, the calyx can be entered again and again without the wire having to be replaced.

On occasion, a stone can be visualized with the flexible nephroscope, but upon passage of an instrument (such as a basket) through the working sheath, deflection is limited to prevent access to the stone. In this case, with fluoroscopic guidance one can target the stone with the access needle in a direction that dislodges it to a more accessible position. This technique can help achieve a stone-free procedure while avoiding the need for an additional access tract.

Another tip mentioned earlier is placing a flexible ureteroscope through the rigid nephroscope. This is particularly useful when the infundibulum to the targeted calyx is narrow and will not accommodate a flexible nephroscope. The smaller girth of the flexible ureteroscope means it can enter almost all calyces, but maneuvering these scopes in the collecting system can be challenging because of poor irrigation through their small working channels, their excessive length, their tight radius of curvature, and their lack of torque stability. By visualizing the infundibulum with a rigid scope, the flexible ureteroscope can be guided into the calyx by a second surgeon through the working port of the rigid scope, which the first surgeon holds steady. Once the calyx is entered, the camera can be switched to the flexible scope. Alternatively, two video towers can be employed so that simultaneous views from the rigid and flexible scopes can be obtained.

Finally, as all visualized stone pieces are cleared, it is customary to evaluate the kidney with fluoroscopy to assess for residual radiopaque fragments [15]. At times, it can be challenging to differentiate a possible stone fragment from overlying structures. In this scenario, it is useful to move the kidney by gently maneuvering the access sheath inferiorly or superiorly; radiopacities that move with the kidney suggest residual stone.

## Conclusions

Advances in flexible nephroscopy and instruments available for percutaneous renal procedures have made it possible to perform surgery more efficiently and safely. Many of the instruments and techniques discussed increase access to difficult calyces during percutaneous renal procedures and reduce the need for additional percutaneous access. It is hoped that the techniques outlined in this chapter will help urologists to expand their indications for flexible nephroscopy, increase their comfort level with new scopes and accessories, and attempt the techniques before adding another access during a difficult percutaneous renal procedure.

*Department of Urology, School of Medicine, Ege University, İzmir, Turkey*

## Introduction

The optimal treatment for large proximal ureteral stones remains controversial. Treatment for ureteral stones includes shock-wave lithotripsy (SWL), semirigid/flexible ureteroscopy (URS), percutaneous antegrade URS, open and laparoscopic surgery. Each modality has its advantages and disadvantages. SWL is noninvasive, can be utilized as an outpatient procedure and is associated with low morbidity. However, it has a limited role in managing large, impacted upper ureteral stones, due to its low success rate and high retreatment rate [1]. Retrograde URS is recommended as first-line treatment for ureteral stones >10 mm [2]. However, treatment of proximal stones is associated with higher intraoperative complication and retreatment rates compared to distal stones [3]. On some occasions, proximal ureteral stones are unlikely to be accessible with URS due to tortuosity and angulation of the ureter or other anatomic abnormalities (Figure 23.1a,b). Moreover, flexible URS requires specific instrumentation and expertise and is costly. Percutaneous antegrade URS is an effective alternative when SWL and/or retrograde URS are not indicated or have failed [4–6]. In rare cases, patients with large or complex stones and/or coexisting anatomic abnormatilites may better be suitable for open or laparoscopic surgery [7, 8]. In this chapter, we describe perioperative considerations, surgical technique, and clinical outcomes of antegrade percutaneous URS.

## Indications

The antegrade approach may be most useful for patients in whom retrograde access is difficult or challenging (Figure 23.2a,b). Prior access failure, large and obstructing ureteral stone burden, concomitant ureteral and renal stone, pediatric patients, prior bladder or ureteral surgery, large median lobe of the prostate, transplanted kidneys, prior urinary diversion with ileal conduit, heterotopic, or orthotopic diversion are scenarios for which antegrade access may provide higher success rates and prove more efficient.

## Contraindications

Uncorrectable bleeding diathesis, ipsilateral kidney tumor, pregnancy, and untreated urinary tract infection are contraindications to percutaneous renal surgery. All attempts should be made to ensure sterile urine and correct bleeding diathesis prior to the procedure.

## Preoperative assessment

Proper preoperative imaging includes computed tomography (CT) for comprehensive evaluation of stone size, position, composition, degree of hydronephrosis, and surrounding anatomy. Evaluation of the CT characteristics allows selection of the preferred calyx for access. Presence of severe renal atrophy should prompt a functional imaging study to determine differential renal function. If stone size is large and renal function is poor, the option of simple nephrectomy or therapeutic nephrostomy can be entertained. A comprehensive discussion including risks, benefits, and alternatives should be undertaken and informed consent obtained.

Preoperative laboratory evaluation should include baseline renal function, serum electrolytes, blood count, platelets, and coagulation factors. Blood type and screen for crossmatch should also be obtained. Antiplatelet agents should be discontinued at least 5 days prior to the

procedure and heparin or low molecular weight heparin can be substituted preoperatively for warfarin. A urine culture should be obtained preoperatively and, if positive, sensitivity-specific antibiotics should be administered. Repeat urine culture should ensure sterile urine. If sterile urine can not be achieved by antibiotics, preoperative percutaneous nephrostomy should be considered. Once sterile urine is present, prophylactic antimicrobial coverage should be administered prior to anesthesia and continued perioperatively.

## Percutaneous antegrade ureteroscopy technique (proximal ureteral stones)

Instrumentation required for the procedure is listed in Table 23.1.

Following induction of general anesthesia, a 22 Fr rigid cystoscope is inserted transurethrally and used to place 6 Fr open-ended ureteral catheter to the ipsilateral renal collecting system in the lithotomy position. If the stone does not allow passage of the ureteral catheter into the renal pelvis, the catheter is placed a few milimeters below the impacted stone. Position is confirmed using fluoroscopy. A retrograde pyelogram using the catheter delineates collecting system anatomy. Special considerations regarding inappropriate retrograde pyelogram in the presence of impacted stone or other situations are discussed below. Foley catheter is inserted, the ureteral catheter is then fixed to the Foley in order to prevent catheter dislodgement.

**Table 23.1** Instrumentation required for antegrade percutaneous ureteroscopy.

| Instrument/disposable | Quantity |
|---|---|
| 15.5 Fr flexible cystoscope | 1 |
| 7.5 Fr flexible ureteroscope | 1 |
| 24 Fr rigid nephroscope | 1 |
| 0.038-inch PTFE-nitinol guidewire with hydrophilic tip | 2 |
| Amplatz super-stiff guidewire | 1 |
| Cystoscopic camera | 1 |
| Light cord | 1 |
| Pressure bag/saline irrigation | 1 |
| Video tower | 1 |
| Nitinol stone basket | 1 |
| Holmium:YAG laser | Optional |
| 272 micron holmium laser fiber | Optional |
| 10 Fr dual lumen ureteral catheter | 1 |
| 18 gauge percutaneous access needle | 1 |
| 8/10 coaxial dilator | 1 |
| C-arm fluoroscope | 1 |
| 30 Fr Amplatz serial dilators/nephroscopic sheath | 1 |
| 11/13 ureteral access sheath | Optional |
| Ultrasonic lithotripter | 1 |
| Pneumatic lithotripter | 1 |
| Nephroscopic grasping forceps | 2 |
| 26 cm 6 Fr double-J ureteral stent | 1 |
| 8 Fr nephrostomy tube | Optional |
| Surgical lubricant | 1 |
| Radiologic contrast material | 1 |
| Small containers for saline and for radiographic contrast material | 2 |
| 10 ml syringes | 2 |

The patient is then turned prone. Under fluoroscopic guidance, a disposable 18 gauge access needle is advanced percutaneously into the calyx of choice. Access is achieved through the middle calyx or the upper calyx in order to have direct access to the renal pelvis and the ureter; the upper calyx provides more direct access but more risk of thoracic complications. The aim is to get a short, straight percutaneous tract to the upper ureter and the calculus. Our technique for access involves targeting the preferred site in the anteroposterior plane as well as the oblique plane. Needle placement is confirmed and a 0.038-inch PTFE-nitinol guidewire with hydrophilic tip is advanced into the calyx. At this point, the skin is incised sharply around the cutaneous entry point and the access needle is removed. Clear urine efflux confirms correct entry. After percutaneous renal access is obtained, the next important step is proper dilation and establishment of a nephrostomy tract. An 8 Fr/10 Fr coaxial dilator is passed over the percutaneous wire to the proximal ureter and used to place an Amplatz super-stiff guidewire as a second wire. The access tract is dilated along the guidewire using a series of Amplatz dilators up to 30 Fr (20 Fr if a mini-percutaneous nephrolithotomy (mini PCNL) technique is elected). The choice of use of standard nephroscope versus mini-nephroscope is at the discretion of the surgeon. Once the tract is dilated to 30 Fr (20 Fr for mini PCNL), the accompanying sheath can be gently advanced over the dilator using fluoroscopic control to confirm proper positioning within the collecting system. A 24 Fr (17 Fr for mini PCNL) rigid nephroscope is then advanced into the collecting system and the stones are treated with a combination of pneumatic and/or ultrasonic lithotripsy as well as intact fragment removal (Figure 23.3). Care is taken not to fragment the stones into very small pieces, as this will make stone extraction difficult. If the proximal ureteral stone is visible but not accessible with a rigid nephroscope, a 8 Fr semirigid ureteroscope or a 15.5 Fr flexible cystonephroscope is used. On some occasions, a 7.5 Fr flexible URS can be used during or following nephroscopy in order to aid in lithotripsy as well as to ensure stone-free status where distal ureteral access is difficult. Following PCNL a 0.038-inch guidewire may be placed in an antegrade manner through the nephroscope and down the ureter. The access sheath is removed, the distal portion of the wire is curled in the bladder, and a 26 cm double-J ureteral stent is advanced through the nephroscope and positioned appropriately. Depending

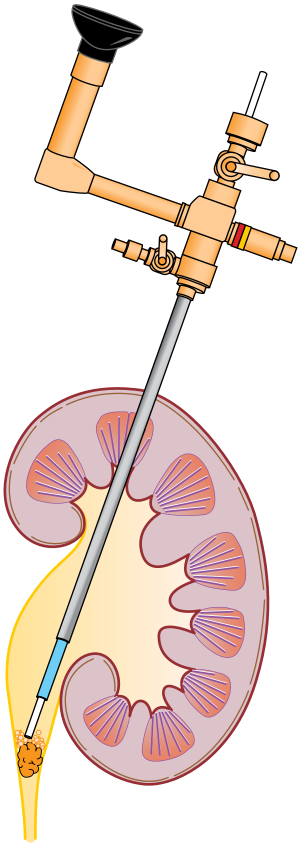

**Figure 23.3** Diagrammatic representation of percutaneous antegrade ureteroscopy. The rigid nephroscope is directed towards the proximal ureter and the stone for pneumatic lithotripsy. Note that percutaneous tract to the upper ureter and the stone is in a straight line.

upon the ease of the procedure as well as the confidence in a stone-free status, the placement of a nephrostomy tube can be elected.

A mini PCNL procedure rather than standard PCNL can be elected to perform an antegrade percutaneous URS in order to decrease the morbidity of the procedure. The principles are the same as standard antegrade URS. Mini PCNL is performed with a miniature nephroscope (i.e. 17 Fr nephroscope) via a smaller percutaneous tract (<20 Fr).

## Percutaneous antegrade flexible ureteroscopy technique (distal ureteral stones)

Percutaneous access is performed under fluoroscopic guidance in the prone position. The upper calyx is preferred for more distal ureteral pathology. If a nephrostomy is already in place, a guidewire is placed to the collecting system under fluoroscopic guidance. A second guidewire (safety wire) is introduced with the use of a double-lumen catheter into the ureter. Tract dilation is peformed up to 14 Fr with Amplatz dilators. A 11–13 Fr ureteral access sheath is inserted, under fluoroscopy, into the ureter over the guidewire. A 7.5 Fr flexible ureteroscope is inserted under endoscopic vision. The stone is visualized in the distal ureter and fragmented with holmium:yttrium–aluminum–garnet (YAG) laser under endoscopic vision. An access sheath provides low pressure in the collecting system and easy re-entry of the flexible ureteroscope. A nitinol basket is used to extract any significant fragments. A 6 Fr double-J stent is placed in an antegrade fashion and/or a 8 Fr nephrostomy tube is left in place.

## Special considerations

One of the challenges when using the antegrade approach is to perform retrograde pyelogram for impacted ureteral stones and in difficult ureteral access scenarios (i.e. prior urinary diversion). If a ureteral catheter cannot be advanced from the distal ureter or impacted stone, there are several options to opacify the collecting system for further percutaneous renal access. One option is to use an ultrasound for initial access (requires expertise). Percutaneous renal access allows for antegrade injection of contrast material to help delineate anatomy and points of obstruction. The second option is to administer the contrast by intravenous route. CT-guided access preoperatively is necessary in select cases. Lastly, the large impacted stone can initially be treated ureteroscopically to open a little window between the stone and the ureter and a guidewire is passed to the renal pelvis. A 4 Fr ureteral catheter is then placed over the guidewire into the collecting system.

## Postoperative care

Routine blood tests, including hemoglobin, are obtained postoperatively and a chest X-ray is performed in cases with supracostal access. After performing the antegrade technique, our preference is to leave the Foley catheter for one day and the double-J stent for approximately two weeks and then to remove the stent using flexible cystoscopy in the outpatient clinic. In complicated cases, we also leave a 8 Fr nephrostomy tube and remove it on postoperative days 2–3 after confirmation of normal nephrostogram. Patients are followed in an outpatient setting with a noncontrast CT at one month post operation in order to assess for residual stones.

## Percutaneous antegrade ureteroscopy outcomes

There have been several published reports since the first description of percutaneous antegrade URS by Gumpinger et al. [9]. In this initial report, 22 patients were managed by percutaneous antegrade URS technique with a stone-free rate of 100% after one session. Several other centers demonstrated the efficacy and safety of this technique [10, 11]. In these series, percutaneous antegrade URS was performed for large stones (>15 mm) that were densely impacted and located between the ureteropelvic junction and the lower border of the fourth lumbar vertebra. Most patients (>90%) were stone-free in a single session through a single tract without any major complications.

Location of the ureteral orifices, access to the ureter, and subsequent retrograde ureteroscopy are challenging in patients after any form of urinary diversion. However, these patients are at risk of developing urinary stones due to various anatomical and metabolic causes. El-Nahas et al. have elegantly demonstrated that percutaneous treatment of large upper tract stones after urinary diversion offered an effective treatment with minimal morbidity in 24 patients [6]. The challenges of retrograde ureteral access in patients with prior urinary diversion makes antegrade percutaneous URS an ideal management strategy in this patient cohort, as demonstrated in our video (see Video 23.1).

Table 23.2 summarizes the prospective and retrospective comparative series [12–21]. Most of these series have been published by high-volume Chinese centers. They demonstrate excellent rates of stone clearance in one session with acceptable morbidity. Antegrade access to the ureter, though minimally invasive, has the potential risks of hemorrhage, sepsis, pneumothorax, and other complications associated with percutaneous surgery.

Comparison of outcomes from pure antegrade and retrograde URS were evaluated in seven series [12, 13, 15–17, 20, 21]. Notably, semirigid URS was utilized in most patients. These studies demonstrated low morbidity with infrequent minor complications and no major complications in patients treated with antegrade URS. A criticism of antegrade URS compared to retrograde URS includes its more invasive nature. Its use can be justified because of the higher stone-free rates in a single session.

**Table 23.2** Comparative outcomes for minimally invasive surgical management of proximal ureteral stones.

N/A, not available; URS, ureteroscopy; PCNL, percutaneous nephrolithotomy; fURS, flexible ureteroscopy; mini PCNL, mini-percutaneous nephrolithotomy; Lap, laparoscopy.

However, it may be possible to achieve better outcomes with use of current-era flexible ureteroscopy and lithotripsy, albeit at higher cost.

Although antegrade URS techniques are generally standardized, Chinese centers mainly use mini PCNL, whereas other centers prefer standard PCNL instrumentation. In a recent meta-analysis comparing PCNL with flexible URS, standard PCNL was associated with higher stone-free rates at the expense of higher complication rates, whereas flexible URS provided higher stone-free rates than mini PCNL [22].

Hu et al. have recently compared the effectiveness and safety of mini-percutaneous antegrade URS to the retrograde flexible URS in 179 elderly patients with medium-sized renal and ureteral stones [21]. No significant differences were found in terms of complications, but a statistical trend in favor of URS was observed. The overall stone-free rate was higher with mini PCNL for multiple stones, but similar for solitary stones.

Retrograde, antegrade, and laparoscopic approaches were compared for management of proximal ureteral stones in two series (Table 23.2) [14, 18]. When taking into account both efficacy and safety, the antegrade approach provided more advantages compared to the other two techniques. Importantly, an additional benefit includes the availability of PCNL instrumentation and technique in most urology units.

## Conclusions

The antegrade technique for ureteroscopy can provide several advantages over an exclusively retrograde approach, especially in cases in which retrograde access is challenging. Its invasive nature and undefined degrees of benefit limit our ability to recommend an antegrade approach routinely for all proximal ureteral stones. Careful patient selection and preparation, as well as familiarity with instruments and techniques, help to increase the efficacy and decrease the morbidity associated with antegrade ureteroscopy.

# Small-caliber Percutaneous Nephrolithotomy: Mini, UMP, and Micro-Perc

*Janak D. Desai*[1] *& Arkadiusz Miernik*[2]

[1] *Samved Hospital and Sterling Hospitals, Ahmedabad, India*
[2] *Division of Urotechnology, University of Freiburg – Medical Centre, Department of Urology, Freiburg, Germany*

## Introduction and instrumentation including miniaturization

The story of percutaneous nephrolithotomy (PCNL) began in 1941 when Rupel and Brown of Indianapolis, removed a stone through a previously established surgical nephrostomy track [1]. Fernstrom and Johannson first reported the establishment of a percutaneous track with the specific intention of removing a stone [2]. Thereafter advances in endoscopes, imaging equipment, and stone disintegration devices allowed urologists to refine these percutaneous techniques through the late 1970s and early 1980s into well-established methods for removal of upper urinary tract calculi. The development of minimally invasive surgical techniques for the treatment of patients suffering from urinary lithiasis has been greatly dependent on technologic advances in the fields of fiber-optics, radiographic imaging, and intracorporeal lithotripsy (mainly novel and highly efficient laser emitters). These advancements have accelerated the evolution of modern techniques of calculus removal, including mini PCNL, ultra-mini PCNL (UMP), and micro-perc.

In general, the percutaneous treatment of kidney stones might be considered to be relatively invasive, in particular considering substantial perioperative morbidity such as bleeding and infection rates [3]. An extended analysis can be found in a publication on PCNL initiated by the Clinical Research Office of the Endourological Society (CROES) [4].

With regard to the perioperative morbidity of PCNL, a phenomenon related to the size of Amplatz sheath has been observed: the most feared complication of bleeding increases directly depending on larger volume of the access tract [4]. In order to improve perioperative safety of percutaneous stone treatment several clinical studies have been conducted and modifications made.

The history of percutaneous access to renal pelvis is long and fascinating. Three decades ago when Alken laid down the steps of renal dilation the endoscopic companies made instruments that helped us view the pelvicalyceal system and bring out the stones [5]. Surgeons in the United States subsequently used a track size of almost 38–40 Fr, mainly because the disintegration devices were not well developed and large pieces of stones had to be removed intact through a large Amplatz sheath [6]. It was soon observed that 38–40 Fr dilation was just too large and therefore Kurt Amplatz and Arthur Smith settled on an Amplatz size of 30 Fr for standard PCNL. Thereafter many scientific articles stated that if we could reduce the track size the bleeding would be less, the parenchymal damage would be reduced, and the recovery time would be shortened. Sven Lahme in Germany proposed in his paper published in 2002 that a track size of 20 Fr could easily remove renal stones and by reducing the dilation we could reduce bleeding and damage [7]. This was called mini PCNL. Smaller size nephroscopes and sheaths were made by instrument makers and many urologists across the world embraced the concept of mini PCNL [8].

In parallel, Udo Nagele proposed a similar concept called minimally invasive percutaneous nephrolitholapaxy (MIP) [9]. The main focus of this development was on avoiding high-pressure peaks (over 30 $cmH_2O$) during percutaneous _ procedures, which might lead to pyelovenous reflux and fluid overload. Such conditions may be the reason for PCNL-related infectious complications such as sepsis [10].

In 2010, Janak Desai and colleagues in India developed what they called ultra-mini PCNL (UMP). The first articles on UMP were published in 2013 [11, 12]. UMP involves a telescope of 1 mm size and a sheath size of either 11 Fr or 13 Fr. The sheath has a special design that helps to remove the fragments by creating a mini whirlpool effect in the pelvicalyceal system. This moves the stone

fragments from a high-pressure zone to the sheath, which is a low-pressure zone (Figures 24.1 and 24.2) [12]. In 2010 Shaft and Bader developed a needle nephroscope called an “all-seeing needle” [14]. It is 4.85 Fr in size and the puncture is performed in a single-step setting. M. Desai added a modification that enabled passing a laser fiber to disintegrate the stone [14]. Since the stone fragments are not removed we have to wait for natural expulsion of these fragments. This technique was called micro PCNL. Thus from conventional PCNL we have now arrived at a stage where mini PCNL, ultra-mini PCNL, and micro-perc can remove most kidney stones.

## Mini PCNL and minimally dilated punctures

The “mini-perc” technique was first developed for use in children. An 11–15 Fr peel-away vascular access sheath was used, instead of the more commonly used 24–30 Fr Amplatz sheaths [15]. The mini-perc technique was adapted to adult patients with stones smaller than 2 cm by use of a 13 Fr ureteroscopy sheath for percutaneous access and a 6.9 Fr rigid ureteroscope. Lithotripsy was achieved with a thin ultrasonic probe or a holmium:YAG laser. The authors reported a stone-free rate of 89% with minimal morbidity. Monga and Oglevie used a 20 Fr nephrostomy sheath, and a 9.8 Fr rigid endoscope and reported similar results in a series of 16 patients with an average stone size of 2.8 cm [16]. Several papers have shown the advantage of minimally dilated punctures and the procedures in that ambit are: mini PCNL, ultra-mini PCNL (UMP), and micro-perc [7, 8, 17].

## Classification of different PCNL systems

Different classifications of particular PCNL systems have been introduced by the manufacturers and developers of this technology. Until now there has been no general unified description system reporting on PCNL.

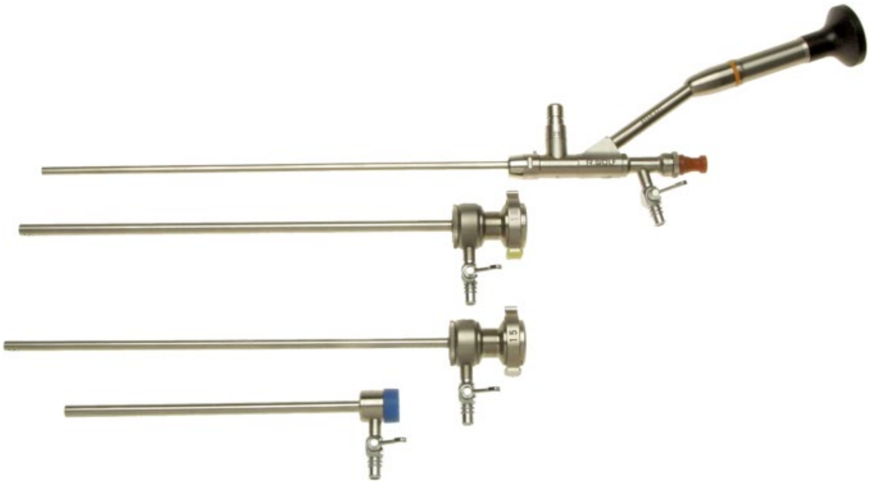

**Figure 24.1** Mini PCNL set according to Lahme. The system consists of a pediatric metallic shaft, 15 Fr adult shaft, 18 Fr adult shaft, and a nephroscope. *Source:* Richard Wolf GmbH, Knittlingen, Germany. Reproduced with permission of Richard Wolf, Germany.

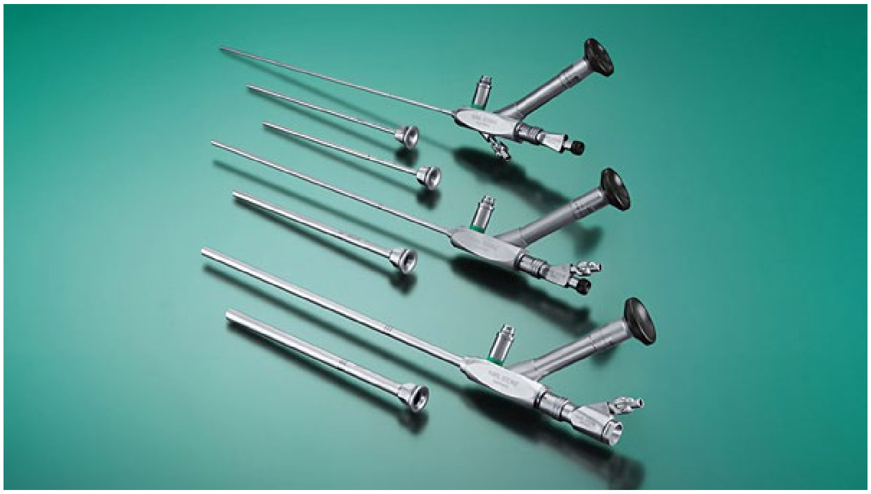

**Figure 24.2** Novel PCNL system including minimally invasive PCNL (MIP) set according to Nagele. *Source:* Karl Storz, Tutlingen, Germany. Reproduced with permission of Karl Storz.

The systems are mainly named according to the outer diameter of the Amplatz shaft. In the last consensus guideline on urolithiasis by the German Association of Urology [18] the following classification was published:

- Standard PCNL: 24–32 Fr
- Mini PCNL: 14–22 Fr
- Ultra-mini PCNL: 11–13 Fr
- Micro PCNL: 4.8–11 Fr.

Other literature sources suggest using the name “mini PCNL” for systems using access sheaths smaller than 20 Fr [19] and “micro PCNL” for tract size 11 Fr or less [20].

Because of the growing number of names and descriptions the proper allocation of a particular technique might still be confusing for urologists. Wright et al. proposed a unified classification for devices used in percutaneous stone treatment (Table 24.1) [21]. As well as sheath size, the approach, fragmentation method, and postoperative drainage of the urinary track should be systematically reported.

## Mini PCNL

Several papers have been published describing the advantages of reducing track size [22], reporting that the amount of bleeding is less, the parenchymal damage is less, and length of hospitalization is reduced (Table 24.2). However, the mini PCNL technique requires longer operative time for fragmentation of relatively small, otherwise extractable stones. It is still under debate whether the track of 18–22 Fr (mini PCNL) does significantly less damage than a track of 28–30 Fr (standard PCNL).

The instruments consist of a thinner nephroscope and instead of the Amplatz sheath, three different sizes of metal sheaths are available. The sheaths are approximately 18 Fr, 21 Fr, and 24 Fr outer diameter. The stone disintegration can be carried out by pneumatic energy or ultrasonic energy and the extraction can be carried out by thinner forceps. If the stone load is less, the fragments can be brought out using fluid dynamics.

**Table 24.2** Transfusion rates in relation to sheath size in percutaneous nephrolithotomy [4].

| Sheath size | No. of patients | Blood transfusion (*n* (%)) |
|---|---|---|
| Small (18 Fr and below) | 271 | 3 (1.1%) |
| Medium (24 Fr and 26 Fr) | 1039 | 50 (4.8%) |
| Large (27 Fr, 28 Fr, and 30 Fr) | 3533 | 208 (5.9%) |
| Largest (32 Fr, 33 Fr, and 34 Fr) | 371 | 45 (12.1%) |

## Ultra-mini PCNL (UMP)

There was an observation that renal parenchyma is resilient enough to withstand a dilation of up to 14–15 Fr. If the dilation is done beyond 15 Fr, the parenchyma may give way to small lateral tears. These tears lead to bleeding and renal damage. The ultra-mini PCNL (UMP) is designed to limit dilation to either 11 or 13 Fr. A set of specially designed instruments include a telescope of 1 mm size that has a resolution of 17 000 pixels; an inner sheath of 6.0 Fr, which has two ports (one for irrigation and the other for a laser fiber); and an outer sheath of 11 or 13 Fr with a side-port that connects to a very thin tube running parallel to its lumen (Figure 24.3).

The stone disintegration is done with a holmium laser of 200 or 365 μm and the aim is to make small fragments of 1.5–2.0 mm. Because the aim is not to turn the stone to dust, the laser setting involves high energy (12 W) and low frequency (8 Hz). The disintegration is slower than in standard PCNL so this technique is limited to removing stones of medium or low bulk (less than 1.8 cm). At the end of disintegration, the stone fragments are removed by creating a mini whirlpool of saline by injecting through the side-port of the outer sheath (see Video 24.1).

Alternatively, a vortex can also be created by injecting saline through the previously placed ureteric catheter. The fluid moves from a high-pressure zone (i.e. pelvis and calyces) to a low-pressure zone (i.e. the lumen of the outer sheath). The saline jet through the small side-tube

**Table 24.1** Proposed terminology for defining percutaneous nephrolithotomy procedures [21].

| Approach | Sheath size (Fr) | Fragmentation method | Drainage |
|---|---|---|---|
| P = Prone | 4.8–34 | Li = Lithotripsy | N = Nephrostomy |
| S = Supine | | U = Ultrasound | S = Stent |
| | | La = Laser | NS = Nephrostomy and stent |
| | | EHL = Electrohydraulic lithotripsy | TT = Totally tubeless |

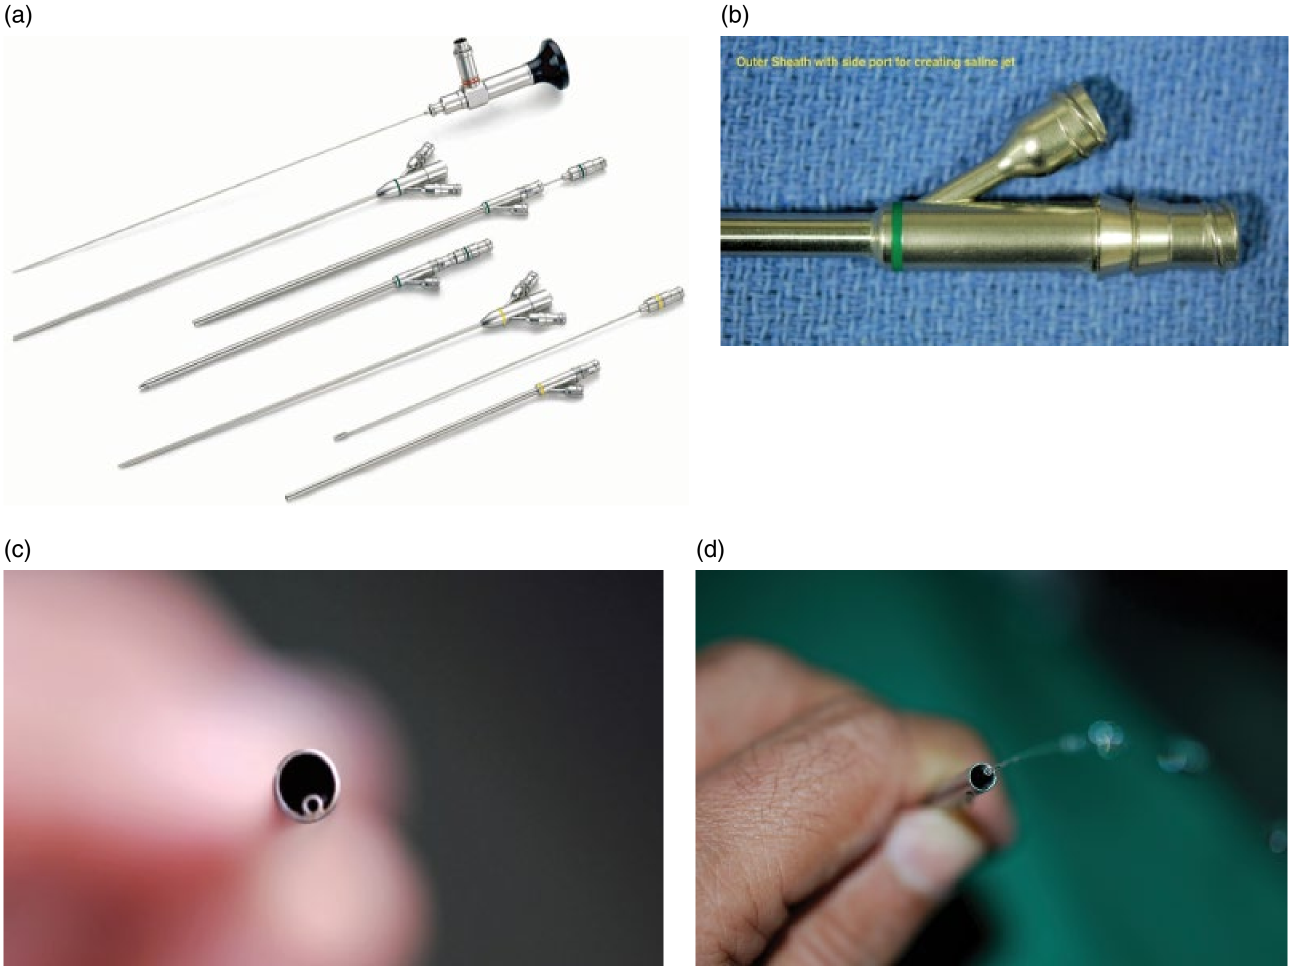

**Figure 24.3** UMP instruments. (a) Full ultra-mini PCNL set consisting of 11 and 13 F shafts and dilatators as well as a miniaturized nephroscope. (b) Outer sheath with a side-port connecting to the waterjet tube inside. (c) View of waterjet tube inside the sheath. (d) Demonstration of the "waterjet" function. Reproduced with permission of Schoelly Fiberoptics GmbH, Denzlingen, Germany & Dr. Janak Desai.

is required to agitate the dormant fragments and bring them into the vortex. Often the fragments will be evacuated automatically by the vortex; however, in certain situations a low suction can be placed on the end of the outer sheath to pull out the fragments. The mini whirlpool effect can be viewed in the small video (see Video 24.2). The endoscopic view is captured by a flexible ureteroscope. When a jet is created by pushing saline through the side-port of the outer sheath, the fragments get trapped in the saline vortex and move towards the main lumen of the outer sheath.

The UMP procedure can be used as a primary procedure for low- and medium-bulk stones or as an adjunct procedure during staghorn calculus removal. A small stone in a different calyx may be removed by UMP (instead of doing a procedure with a larger second track).

The advantages of UMP over retrograde intrarenal surgery (RIRS) are the relative speed of the procedure and the use of minimal disposables. The advantage in terms of stone-free rates needs to be established. UMP and RIRS are compared in Table 24.3 [23]. These data accrue from a few initial users of UMP and need to be verified by the urological community at large.

## Micro-perc

This technique consists of puncture with a needle telescope which is 0.9 mm thick (Figure 24.4). It is a flexible fiber-optic scope that has 10 000 pixel resolution and the needle is 16 gauge thick. The puncture is done with the help of sonography and/or fluroscopy guidance and once the needle enters the system the stone can be visualized directly. With a 200 μm holmium laser fiber the stone is disintegrated and converted into dust/fragments. These fragments are then expected to pass spontaneously. To prevent a rise in intrarenal pressure during the procedure, a 8.0 Fr ureteric catheter is placed at the beginning.

**Table 24.3** Comparison between ultra-mini percutaneous nephrolithotomy and retrograde intrarenal surgery [23].

| | RIRS | UMP |
|---|---|---|
| Total cases | 20 | 32 |
| Operation time (min) | 98 | 46 |
| Hospitalization (h) | 32 | 24 |
| Cost of disposables (euros) | 484 | 80 |
| Complication rate | 8% | 6% |
| Stone-free rate | 80% | 88% |
| Auxiliary procedure | 100% | 1% |
| Fever (percentage of patients) | 20% | 12.5% |

UMP, ultra-mini percutaneous nephrolithotomy; RIRS, retrograde intrarenal surgery.

This large-bore ureteric catheter is expected to drain the kidney and keep the pressures within acceptable limits [24].

Micro-perc is a useful procedure but the main drawbacks are as follows: (i) Puncture with a thicker needle – 16 gauge (1.65 mm) can happen. Each pass leads to relatively more damage than the pass of a 20 (0.9 mm) or 18 gauge (1.27 mm) needle. Although there a telescope positioned within the needle, the telescope starts viewing only when it has reached within the calyx. Prior to that time it sees only red. (ii) Following stone disintegration the procedure relies on nature for stone expulsion. Unlike other PCNL procedures, stone extraction is not possible with this thin apparatus. It can be used judiciously for small stones which are in the calyces or the renal pelvis. Stones trapped in closed calyces cannot be removed by micro-perc because the fragmented stones cannot escape to the pelvis through the extremely narrow infundibulum. Nevertheless, micro-perc can be a good procedure for pediatric patients and also as an adjunct to removal of larger stone bulk in adults, where a small stone is located in the other calyx that cannot be approached by the regular nephroscope.

The advantages of micro-perc as compared to extracorporeal shock-wave lithotripsy (ESWL) need to be established [25, 26].

## General considerations regarding miniaturized PCNL

PCNL is characterized by high stone-free rate in treatment of stones in the upper urinary tract, mainly in the kidney. Substantial perioperative complications such as bleeding and sepsis as well as special patient groups (e.g. children) have stimulated further innovations in this field. The driving force behind miniaturization of PCNL was to make this technique applicable in pediatric patients and to decrease morbidity. For about 15 years size reduced devices have been routinely used in clinical management of urolithiasis. New, highly efficient energy emitters such as lasers have made intracorporeal stone disintegration fast and safe. Better irrigation and knowledge of intrarenal pressure conditions could reduce the complication profile and offer similar clinical outcomes (i.e. stone-free rates) [27]. However, minimally invasive

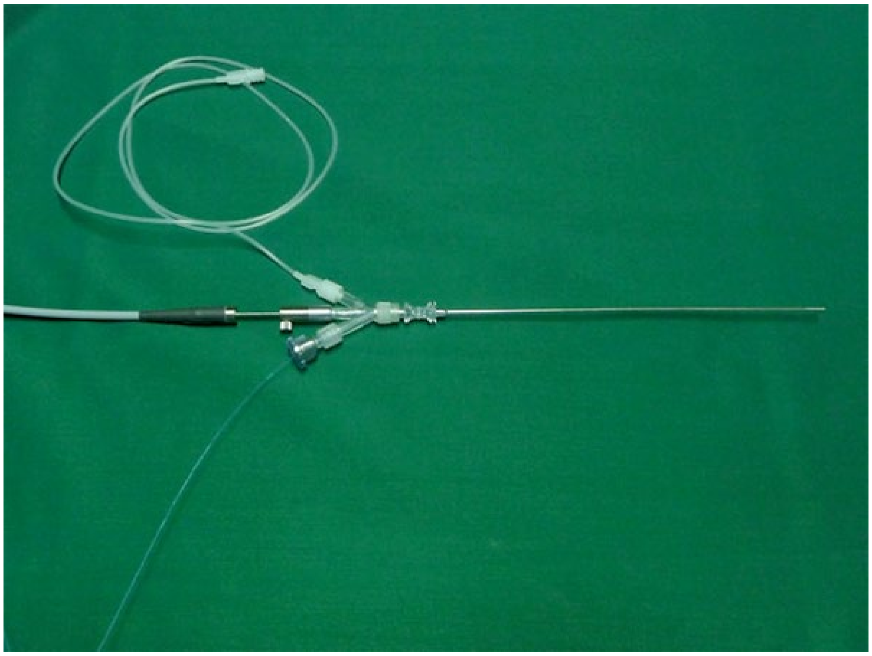

**Figure 24.4** Micro-perc instruments. Telescope within the needle; Connector for irrigation and laser fiber. *Source:* Schoelly Fiberoptics GmbH, Germany (a) and Dr. Janak Desai (b–d). Reproduced with permission of Schoelly Fiberoptics GmbH (a) and Dr. Janak Desai (b–d).

PCNL techiques have to be seen as a further development of the existing standard percutaneous nephrolithotomy procedures.

At least theoretically, miniaturized instruments result in less organ trauma, and thus lower complication rates. On the other hand, manipulation using small devices might be more challenging and associated with longer operating times. Extraction of disintegrated stones might also be more difficult. To address this question high-quality studies are needed. Currently we have scarce and conflicting evidence [28–36].

Zhu et al. published a meta-analysis objectively comparing standard and miniaturized PCNL [37]. Out of 960 studies the authors identified eight trials meeting the inclusion criteria. A data pool was created from three randomized controlled trials (RCTs) (LE: 2b), four prospective case–controls (LE: 3b), and one retrospective case–control study (LE: 3b). The authors assessed the methodological quality as relatively high for all the non-randomized studies and medium for the RCTs [28, 30–36].

### Stone-free rates

The meta-analysis found no difference in stone-free rates between minimally invasive and standard PCNL.

### Hemoglobin decrease and blood transfusion

In the mini PCNL group both hemoglobin decrease and blood transfusion rates were statistically lower than in standard PCNL.

### Operative times and hospital stay

The operating time was shorter in the standard PCNL group. For this analysis data from only seven studies could be evaluated. In contrast, the length of hospitalization was shorter in the mini PCNL group (after data pooling from five trials).

### Postoperative complications

Meta-analysis revealed no differences in terms of fever between the both groups.

### Pain

Using visual analog scale-based data from three studies the postoperative pain perception at day 1 was statistically lower in the mini PCNL group.

### Cost analysis

Two studies analyzed therapy costs, comparing mini PCNL (18 Fr) to RIRS [38] and ultra-mini PCNL (13 Fr) to RIRS [39]. Admittedly, expenses in healthcare might vary widely from country to country and from one healthcare system to another. Schoenthaler et al. [39] analyzed German and British data, whereas Pan et al. [38] investigated the situation in China. Both groups stated that RIRS is significantly more expensive than minimally invasive percutaneous stone treatment. The Chinese study focused on calculi of 2–3 cm, whereas the German–British cohort analyzed medium-size stones (1–2 cm). Looking at clinical outcome, there was no difference in stone-free rates for medium-size fragments. In contrast, mini PCNL was more effective in treatment of the larger 2–3 cm calculi.

## Synopsis

Technically challenging in nature, surgeon experience with PCNL is paramount in developing individualized treatment plans to optimize efficacy with minimal morbidity. A good experience of PCNL is required before taking on minimally invasive modalities such as mini PCNL, MIP, UMP, and micro-perc.

The latest advancements in PCNL technology and clinical introduction of new systems have led to a “revival” of the percutaneous stone treatment. The indication spectrum of PCNL has been tremendously extended and now addresses almost every kidney stone. Despite the continued lack of data from high-quality studies, complication rates seem lower, hospitalization shorter, and stone-free rates comparable to those of conventional, standard systems.

The routine use of the tubeless technique is debatable. Minimally invasive PCNL systems, however, allow lower complications rate if no nephrostomy tube is placed [40, 41].

Bleeding is considered to be one of the most severe complications related to PCNL. The use of miniaturized PCNL systems may help to substantially reduce treatment-associated blood loss. Gazelle et al. [42] demonstrated that larger access sheaths produce more bleeding in an *in vivo* porcine model. Impaired vision and even termination of the procedure might result because of bleeding. Kukreja et al. [43] analyzed various factors potentially related to blood loss. They identified the smaller tracts used in patients with a nondilated pelvicalyceal system or narrow infundibulum, as well as in children younger than 5 years, as one of the factors responsible for lower bleeding rates.

Kidney calculi are conveniently divided into nonstaghorn and staghorn stones, and most controversy is in the area of nonstaghorn stones. For very large stones the treatment of choice is still standard PCNL (with a 28 or 30 Fr dilation). For stones between the sizes of 1.0 and 2.0 cm either UMP or RIRS can be chosen. For stones less than 1.2 cm and where ESWL is not considered a good option, micro-perc can be used.

**Table 24.4** Observational comparison among minimally invasive treatment modalities for kidney stones.

| | Mini PCNL | UMP | RIRS | Micro-perc |
|---|---|---|---|---|
| Cost of equipment | Moderate | Moderate | High | Moderate |
| Learning curve | High | High | Moderate | High |
| Stone-free rate | Good; even for large stones | Good, up to 1.8 cm size stone | Good, up to 1.8 cm size stone | Good, up to 1.0 cm size stone |
| Auxiliary procedure | Almost nil | Almost nil | Stent removal; preprocedure stenting sometimes | Steinstrasse removal sometimes |
| Hospitalization | Two days | One day | One day | One day |

**Table 24.5** Comparison between miniaturized percutaneous nephrolithotomy instruments.

| | Mini PCNL | UMP | Micro-perc |
|---|---|---|---|
| Smallest size of sheath | 17.5 Fr | 11.0 Fr | 4.85 Fr |
| Stone removal | Forceps and fluid dynamics | Creating a fluid vortex | Leave for natural expulsion |
| Telescope size | 3 mm | 1 mm | 0.9 mm |
| Resolution of telescope | 30 000 pixels | 17 000 pixels | 10 000 pixels |

UMP can also be used as an adjunct to standard PCNL; the main bulk can be removed by PCNL and if there is a small stone in an otherwise inaccessible calyx, UMP can be used to remove that stone.

Familiarity with the full spectrum of endourological techniques facilitates a minimally invasive approach to the entire urinary tract.

As the armamentarium of treatment modalities available to the urologist has increased, new controversies regarding the indications for these therapies have developed. Currently, urologists face the challenge of selecting the optimal treatment modality on the basis of the patient's and the stone's characteristics. The choice also depends on the availability of instruments (and thereby experience) in the hospital (Tables 24.4 and 24.5).

Recent technological advances in PCNL might initiate safer and more efficient management of renal stones. A lack of prospective randomized trials comparing treatment modalities coupled with the vast disparity in the access to resources worldwide continues to individualize rather than standardize stone treatment in patients. However, when treating a patient with a renal calculus, the urologist must ask: "Is the patient an appropriate candidate for shock-wave lithotripsy or should other treatment modalities be used?"

## Introduction

A "staghorn" calculus is defined as stone within the renal pelvis extending into two or more calyceal systems. A "partial staghorn," as the name suggests, occupies part, but not all, of the collecting system, while a "complete staghorn" occupies essentially the entire collecting system.

Staghorn calculi composition is commonly struvite (magnesium ammonium phosphate) and/or calcium carbonate apatite. These stone compositions are often referred to as "infection stones" due to their strong association with recurrent urinary tract infections caused by urea-splitting bacteria. Cultures of infection stones have shown that bacteria are harbored within the stone material itself, rather than on the surface [1]. This explains why once an infection stone is present, urine infections tend to recur. Calcium phosphate, uric acid, calcium oxalate, and cysteine also commonly form staghorns, particularly in the metabolic patient. Although traditionally it was thought that the majority of staghorns were infection stones, contemporary studies have shown that metabolic stone staghorns are just as, and perhaps even more, common [2]. Preoperative knowledge of stone composition can potentially play an important role in treatment decisions. The holmium:YAG laser, for example, is a very effective lithotrite for fragmenting struvite stones and less effective for calcium oxalate monohydrate (COM) stones. Cysteine, brushite, and COM stones, for example, are also resistant to fragmentation via shock-wave lithotripsy (SWL).

Possible complications of untreated staghorn calculi include urinary tract infections, sepsis, progressive decline in renal function, renal failure, and death. Traditionally, it has been taught that patients with untreated staghorn calculi have a mortality of up to 30%. This was largely based on the landmark Blandly and Singh study in 1976 which reported a mortality rate of 28% at 10 years for 60 patients managed conservatively for staghorn calculi, compared to a 7% mortality rate for those treated surgically [3]. In 1995, Teichman et al. reviewed 177 patients with staghorn calculi followed for a mean of 7.7 years, and found that no patients with complete stone clearance died of kidney-related causes, compared to 67% of patients who refused treatment [4]. As a result, active aggressive management of staghorn calculi has become the standard of care, with percutaneous nephrolithotomy (PCNL) being the mainstay surgical treatment option. With advances in PCNL technique and its more widespread adoption, as well as better urinary drainage and antibiotic treatment, current mortality rates are likely far lower than initially reported, although a large body of literature on the subject matter is lacking. Furthermore, these older studies involved large cohorts of patients with infection stones, whereas more recent studies demonstrate that the majority of patients have metabolic stones, with lower risks of urosepsis [2, 5, 6]. Recently, Deutsch and Subramonian reported on their single-center experience with conservative management of staghorn calculi in 22 patients [7]. In this small series, patients were managed conservatively due to comorbid conditions, poor access/anatomy, or patient choice. Complications included recurrent urinary tract infections (UTIs) in 50%, progressive renal failure in 14%, disease-specific mortality in 9%, and dialysis dependence in 9%. Disease-specific mortality and morbidity were significantly different between the unilateral and bilateral staghorn groups, at 0 versus 40% and 12 versus 20%, respectively. They concluded that candidates for conservative management would ideally have unilateral asymptomatic stones with minimal infection, in addition to specific indications preventing more aggressive therapy.

The American Urological Association (AUA) best practice guidelines on the surgical management of stones

recommend active treatment of all staghorn stones, if comorbidities do not preclude treatment [5, 6]. Medical therapy and supportive therapy are to be considered only for those not thought to be operative candidates. The 2005 AUA report on the management of staghorn calculi recommends discussion of all treatment options with patients [8]. This includes PCNL, retrograde ureteroscopic approaches (URS), SWL, combined therapies, and open or laparoscopic or robotic surgery, where applicable. PCNL is recommended as the initial modality of choice for treatment of struvite staghorn calculi. This can thereafter be followed by SWL, URS, or repeat PCNL, as required to render patients stone free. In patients not considered candidates for PCNL, clinicians may offer staged ureteroscopy [5, 6]. Unlike adults, the pediatric population has been shown to have great success with SWL in fragmenting even very large stones. In adults, however, SWL and open surgery are not recommended as first-line therapies, with laparoscopic or robotic or open surgery being reserved for situations in which there is expected to be poor success with PCNL and SWL procedures.

The aim of treatment, particularly for struvite calculi, is complete surgical stone removal, as any remaining stone debris may lead to bacterial persistence, recurrent infection, and stone regrowth. Achieving stone-free status also prolongs time to stone recurrence. Stone-free rates for staghorn calculi are widely variable in the literature, but approach 85%, with or without adjunct SWL therapy [9], versus only 51% for SWL monotherapy [10]. Lifshitz et al. reported stone-free rates of 78% with an average of 2.9 procedures [11]. Stone-free rates are lower following PCNL for staghorn calculi, than they are for nonstaghorn stones.

When choosing and planning stone treatment, the urologist must consider stone factors (stone burden, composition, location), renal anatomical factors (obstruction, hydronephrosis, ureteropelvic junction (UPJ) obstruction, calyceal diverticulum, renal ectopia or fusion, lower pole location, reconstructed urinary tracts), and patient and clinical factors (infection, obesity, body habitus, coagulopathy, patient age, hypertension, neurogenic bladder, spina bifida, and renal failure). Current AUA guidelines recommend preoperative workup with computed tomography (CT) of the abdomen and pelvis, urinalysis, urine culture and sensitivity, serum electrolytes, estimated glomerular filtration rate (eGFR), and complete blood count (CBC) [5, 6]. Coagulation parameters are not routinely necessary unless the patient has a history of bleeding diathesis or is on anticoagulant therapy. Further preoperative preparation includes an extended period of antibiotics for actively infected collecting systems and cessation of anticoagulants and antiplatelet agents in preparation for therapeutic procedures. Current AUA guidelines emphasize the importance of obtaining preoperative CT scan in all patients planned for PCNL [5, 6]. In general, a noncontrast CT scan is sufficient, but in patients with anatomic anomalies or UPJ obstruction a triphasic contrast-enhanced CT scan with delayed urographic phase and 3D reconstructions can be very helpful in surgical planning. A differential renal scan can provide clinical useful information, particularly in patients who may have a nonfunctioning kidney with a staghorn stone. They may be better served with nephrectomy (rather than PCNL), particularly for symptomatic or infected stones, and a normal contralateral kidney.

Preoperative assessment of stone complexity is vital, particularly for staghorn calculi. A number of scales have been developed to assess preoperative stone complexity with the aim of predicting postoperative stone-free rates and complications. These scoring systems, such as Guy's stone score [12], S.T.O.N.E. nephrolithometry [13], the CROES nomogram [14], and the Seoul National University Renal Stone Complexity score for PCNL [15], have noted the importance of numerous factors in determining operative success. These include: surgeon case volume, prior stone treatment, presence of staghorn calculi, presence of calyceal diverticula, stone location, stone count, stone size, number of involved calyces, stone density, presence of obstruction, PCNL tract length, anatomical abnormalities, and patient factors (such as spina bifida or spinal injury). These scores, however, are not specific for staghorn calculi. In patients with staghorn calculi, variants of the collecting system anatomy have an important impact on the expected procedural complexity and preoperative, as well as intraoperative, planning. Figure 25.1 illustrates intraoperative images obtained from three patients undergoing PCNL. Figure 25.1a shows a bifid system, which limits the ability to use an upper pole puncture. Figure 25.1b reveals a favorable clinical situation in which the main stone is situated within the renal pelvis, while the calyces are short and dilated. Figure 25.1c shows an unfavorable system with long calyces and relatively narrow infundibula, which will likely require treatment, at least in part, with flexible nephroscopy and laser lithotripsy or multiple punctures to use rigid instruments efficiently and without excessive torque on the renal parenchyma.

Various percutaneous techniques and modifications have been developed with the aim of improving stone-free rates and patient safety. These include variations in patient positioning, number and size of tracts, and instruments for stone removal and fragmentation. In this chapter we review possible difficulties encountered in the treatment of staghorn calculi with PCNL and present our approach, as well as alterative modifications, to treating staghorn calculi via PCNL.

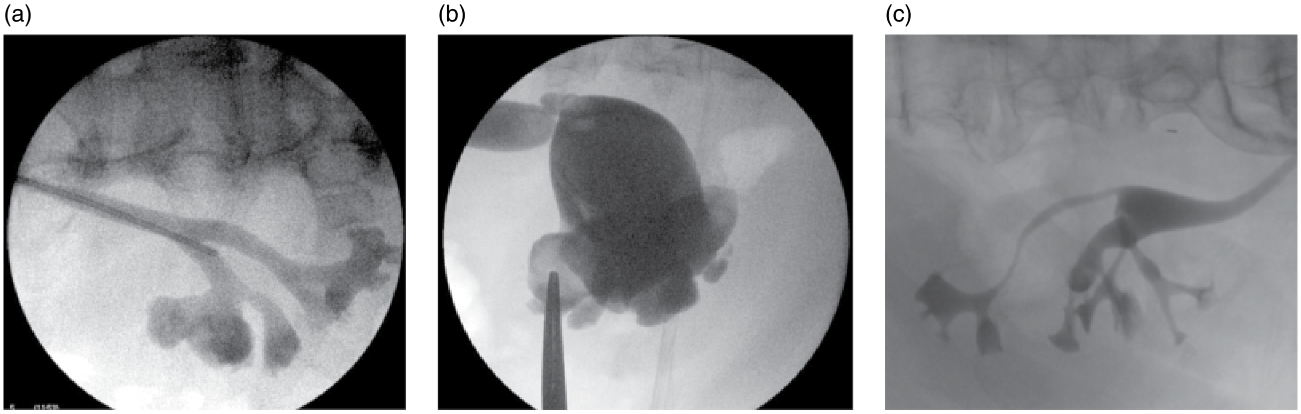

**Figure 25.1** Fluoroscopic images from three patients undergoing PCNL illustrating variation in collecting system anatomy. (a) A bifid system which limits the ability to access the lower pole via an upper pole puncture. (b) A hydronephrotic system with favorable anatomy and short dilated calyces. (c) An unfavorable bifid system with long spidery infundibula.

## Access

Obtaining appropriate access to the pelvicalyceal system is the most challenging and crucial part of PCNL. Technically, access can be obtained by a trained urologist in the operating room or a radiologist preoperatively. Percutaneous renal access, in fact, is not uncommonly performed by interventional radiology preoperatively in the face of obstruction, infection, or complex renal anatomy. Other situations in which radiology-placed access may be quite beneficial include failed retrograde access and inability to opacify the collecting system where fluoroscopic (rather than ultrasound-guided) access is employed, prior urinary diversion which can make retrograde access difficult, or preoperative decompression of an obstructed and/or infected system inadequately drained by stenting. In these cases there should be clear communication between urologist and radiologist to ensure placement of the tract through a posterior calyx ideal for maximizing access to the stone in preparation for PCNL. If the radiologist-placed nephrostomy tube is not ideally placed, it is vital that a new tract be placed intraoperatively, using opacification of the collecting system via the nephrostomy to select and puncture the best calyx (or calyces if multiple tracts are needed).

Urologic surgeon access for PCNL has been shown to be safe and effective. Some studies have reported lower complication rates and improved stone-free rates compared to access obtained by interventional radiology [16]. This can likely be explained by the fact that urologists have intimate knowledge of intrarenal anatomy and angulation of the calyces, the stone complexity, and potential difficulties which can arise during the surgical procedure. Thus, urologists more closely focus on achieving end-on calyceal access through a posterior papilla with a direct access to the stone, as opposed to a potential dangerous tract through the infundibulum or renal pelvis, which, if dilated, can cause significant bleeding and postoperative complications.

Urologist percutaneous access has traditionally been obtained fluoroscopically in the prone position using a bull-seye technique, although various modifications have been developed. Ureteroscopic-assisted puncture, usually in the prone split-leg position, has also recently become more commonplace. Its advantages include the ability to directly visualize a posterior papilla for puncture, as well as decreased fluoroscopy time compared to traditional PCNL [17–19].

Consideration must also be given to the location of the puncture. At our center, we prefer upper pole punctures, when feasible, as this can facilitate single access for staghorn calculi. The upper pole tract tends to be more in line with the axis of the kidney, and allows the efficient treatment of high stone volumes in the upper pole, renal pelvis, and lower calyces with rigid instruments and minimal torque through a single access. The disadvantage, however, of upper pole puncture is that of potential pleural complications. In contrast, although lower pole punctures have a number of advantages including low risk of pleural, liver, and splenic injuries, they involve a longer tract, with a greater skin-to-stone distance, poorer access to the UPJ, and a slightly higher risk of colonic injures. Lower pole punctures are, therefore, more suited for lower pole nonstaghorn stones or lower pole partial staghorns, particularly in bifid collecting systems.

## Patient positioning

Options for patient positioning during PCNL include: prone, prone-flexed, prone split-leg, lateral, lateral-flexed, and supine. The prone position is the standard positioning technique for PCNL. The various modifications to this position change the relative positioning of the kidneys and their surrounding structures, thus altering the incidence of procedural complications.

The prone-flexed position reduces lumbar lordosis and increases working space between the costal margin and iliac crest, which can minimize instrument clashes (Figure 25.2) [20]. In the prone-flexed position, the position of the left kidney is lowered 92% of the time, converting what would have been supra-11th rib punctures in the prone position to supra-12th rib punctures in the prone-flex position 46% of the time, thus minimizing the risk of intrathoracic complications [21]. In addition, the skin-to-kidney distance is shortened (8.4 mm for the right kidney and 13.4 mm for the left kidney) [21]. The kidneys tend to "fall away" from adjacent organs, leading to 11.3° further trajectory to the spleen on the left side and 13.6° further trajectory to the liver on the right side, leading to decreased risk of injury to these organs [21]. Lastly, the prone-flex position sets up an easier trajectory from an upper pole puncture to access the entire collecting system for treatment of staghorn calculi with minimal infundibular torque, as the renal axis is favorably altered in this position. For these reasons, the flexed-prone position is the position most commonly used at our center for PCNL.

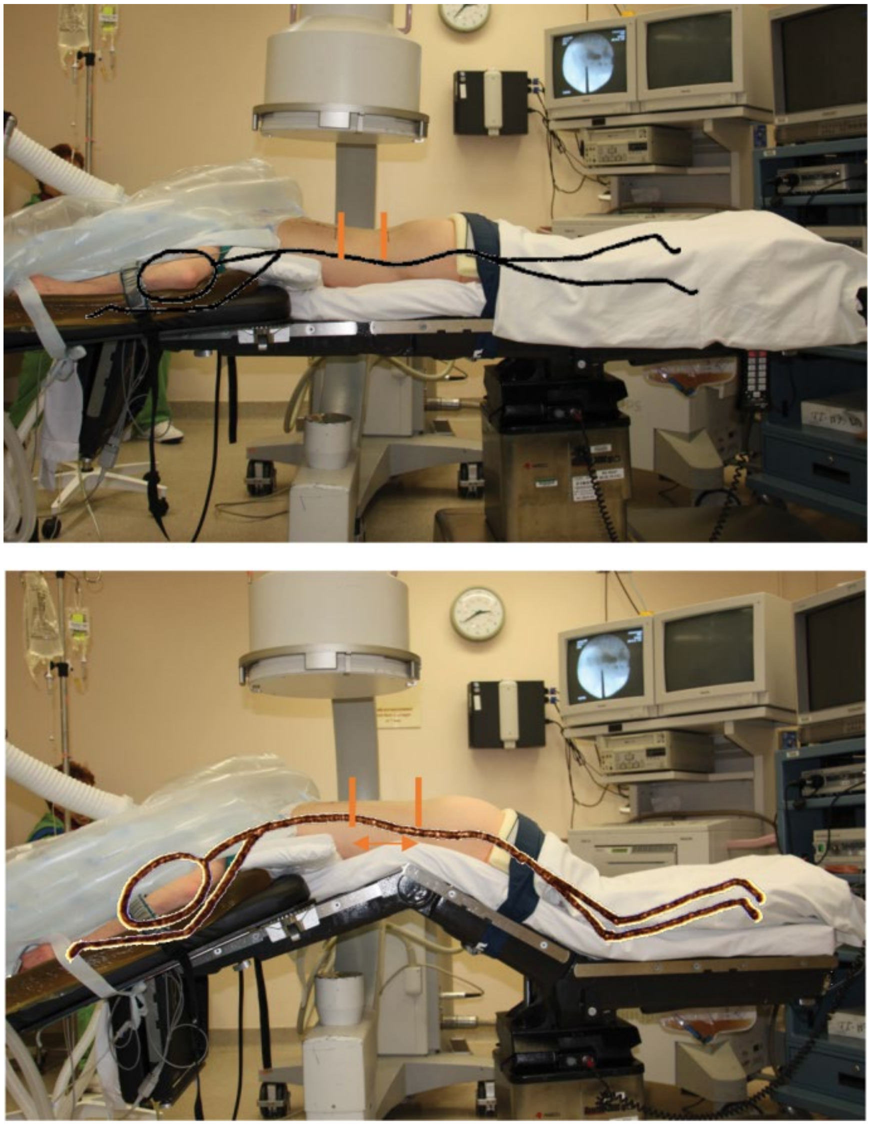

**Figure 25.2** Compared to the prone position, the prone-flexed position for PCNL increases the available flank area for puncture, flattens the back, and decreases instrument clashes with the buttocks. The prone-flex position can thus facilitate the multiple punctures often needed for staghorn calculi. Note the widening of the area between the lines drawn on the flank. *Source:* Ray AA, Chung D, Honey J. Percutaneous nephrolithotomy in the prone and prone-flexed positions: anatomic considerations. *J Endourol* 2009;23(10). Reproduced with permission of Mary Ann Liebert, Inc.

The prone split-leg position is advantageous for performing concomitant retrograde cystoscopy and ureteroscopy without need for repositioning the patient while under anaesthesia. Prone endoscopy, however, has a steep, but easily overcome, learning curve. This positioning also allows for initial attempted treatment via ureteroscopy, in cases where a percutaneous procedure may or may not be necessary and is to be determined based on intraoperative findings.

The lateral and lateral-flexed positions are familiar to urologists as they are often used for open or laparoscopic renal surgery. The most common indications for lateral positioning for PCNL are morbid obesity (due to concerns regarding adequate ventilation in the prone or prone-flexed positions) and skeletal deformities (which mitigate prone positioning). Lateral position has the least effect on cardiac and respiratory function. In addition, the renal pelvis is dependent, providing easier access to mobile stones. The addition of the table flex in the lateral position significantly increases working space and may elevate the lower ribs, reducing the need for supracostal access. In general, the lateral position is more ergonomic for the surgeon, and can be used to perform simultaneous nephroscopy and ureteroscopy. The major disadvantage of this positioning is that fluoroscopic access is technically challenging, as it requires a triangulation technique, rather than the traditional bullseye technique. Ultrasound-guided puncture or radiology-placed access are alternatives. In this position, PCNL can also be successfully performed under spinal anesthetic in patients at high risk for endotracheal intubation.

Supine and modified supine positions (such as the Galdakao-modified supine Valdivia position) are the least common, but are ideal for patient ventilation. They also provide preserved ergonomic access for concurrent retrograde ureteroscopy. In addition, in the supine positioning there is decreased renal mobility, facilitating percutaneous access, particularly to the lower pole. The colon is the furthest away from the kidney in the supine position, and least likely to be injured in this position. This is, however, in part, mitigated by the more lateral placement of the nephrostomy tract which is placed at the anterior axillary line, leading to a longer tract length. Finally, upper pole access is difficult or impossible in the supine position, which limits calyceal selection for the optimal management of more complex staghorn stones.

## Access technique

At our center we begin with the patient in the supine position under general anesthetic with endotracheal intubation. We first perform and save a noncontrast fluoroscopic image to identify the presence and location of the stone(s) before proceeding with flexible cystoscopy and insertion of an open-ended ureteral catheter (5 Fr Flexitip™ ureteral catheter, Cook Medical, Bloomington, IN, USA). The open-ended catheter is advanced toward the renal pelvis, and urine is aspirated to decompress the system. The urine sample is sent for culture and sensitivity. Dye is then injected to obtain a retrograde pyelogram. Anterior–posterior (A-P) and oblique films are taken to identify the three-dimensional calyceal anatomy.

Decompressing hydronephrotic systems, when possible, prevents dilution of the dye and facilitates better opacification, without risk of increased intrarenal pressures and extravasation. Furthermore, should purulent urine be aspirated, the procedure can be stopped at this stage, prior to prone positioning and calyceal puncture. The open-ended catheter is then exchanged over a guidewire (0.035″, 145 cm, fixed-core guidewire, Cook Medical) for a ureteral occlusion balloon catheter (6 Fr, 75 cm, UPJ occlusion balloon catheter set, Cook Medical), which is connected to retrograde flow of contrast. This allows for continuous distention of the collecting system with contrast for eventual fluoroscopic-guided needle puncture. In addition, the balloon catheter prevents migration of stone fragments down the ureter during the procedure and allows for retrograde access later in the case for stent placement. With the retrograde pyelogram performed initially in the supine position, contrast, which is heavier than urine, preferentially enters the posterior calyces, which then appear darker, aiding selection of a posteriorly located calyx for puncture. The targeted posterior calyx is, therefore, initially most easily identified and selected during the supine pyelogram. This is particularly advantageous when there is a hydronephrotic urinary system, which cannot be decompressed prior to dye instillation. In such a system, in the *prone* position, dye will preferentially occupy the anterior calyces, displacing urine in the posterior calyces and making visualization of these calyces difficult fluoroscopically for puncture. In the A-P view, in the *supine* position, posterior calyces are viewed end-on, in line with the infundibulum, and appear dark. As the C-arm is rotated, a posterior calyx will appear to lengthen and move laterally, as the infundibulum comes into view (Figure 25.3) [20].

After placement of the ureteric occlusion balloon and prior to repositioning the patient into the prone-flexed position, a urethral catheter is placed. The catheter balloon is inflated with dye solution and pulled down to the bladder neck, in order to facilitate identification of the bladder neck and placement of a retrograde tethered stent at the end of the procedure. The urethral catheter and ureteral occlusion balloon catheter are secured together.

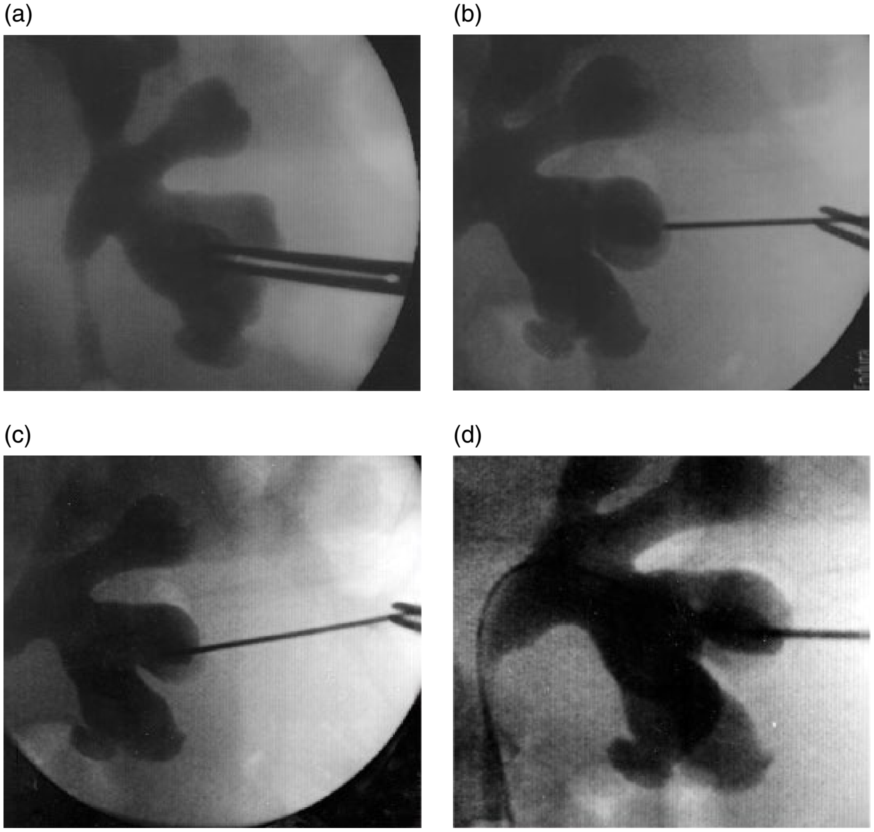

**Figure 25.3** Fluoroscopic images illustrating the bulleye technique of calyceal puncture for a posterior lower pole calyx. (a) "Bullseye" puncture. (b) Needle tip short of calyx. (c) Needle entering calyx. (d) Guidewire down ureter. *Source:* Ray AA, Chung D, Honey J. Percutaneous nephrolithotomy in the prone and prone-flexed positions: anatomic considerations. *J Endourol* 2009;23(10). Reproduced with permission of Mary Ann Liebert, Inc.

The patient is then repositioned in the flexed-prone position. Pressure points are padded, and a bolster is placed under the chest. The C-arm is angled at 0–30° from vertical, and may require further angulation for improved visualization above the 12th rib. An 18 gauge trocar needle (18G, 15cm, trocar needle, Cook Medical) is inserted toward the selected posterior calyx under fluoroscopic guidance, using a bullseye technique. The needle is advanced only during expiration during supracostal punctures to minimize the risk of pulmonary injury. The depth of the puncture is assessed by rotating the C-arm away from the surgeon. The aim is to puncture a posterior-located calyx through the papilla, in line with the infundibulum, thus traversing Brödel's line and minimizing bleeding risk. A "pop" is often felt when entering the collecting system. Once access is believed to be obtained, the inner needle cannula is removed; free flow of contrast confirms successful puncture of the collecting system. Further retrograde dye instillation is then stopped, in order to prevent dye extravasation through the puncture site, which can impair fluoroscopic visualization. An Amplatz extra-stiff guidewire (0.038″, 145cm, Amplatz extra-stiff fixed-core guidewire, Cook Medical) is then inserted through the needle under fluoroscopy. This is ideally aimed down the ureter, beside the occlusion balloon catheter. If this is not possible, an excess amount of wire is curled within the renal pelvis or within a dilated calyx. The skin-to-calyx distance is then measured, the skin incision is enlarged, and the fascia is dilated sequentially to 10Fr using fascial dilators (6Fr, 8Fr, and 10Fr 20cm fascial dilators, Cook Medical). A 10Fr dual-lumen catheter (10Fr, 24cm Flexi-Tip®, dual-lumen ureteral access catheter, Cook Medical) is next advanced over the extra-stiff wire and used to insert a safety guidewire (0.035″, 145cm, fixed-core guidewire, Cook Medical), which is secured to the sterile drape for the remainder of the case. Balloon dilatation of the tract is then performed over the working extra-stiff guidewire (30Fr Ultraxx™ nephrostomy balloon set, Cook Medical) (Figure 25.4). Dilatation of the nephrostomy tract can be performed by balloon dilatation or sequential dilators. Balloon dilation, although more expensive, tends to be faster and less traumatic [22].

## Multiple tracts

Upper pole access has the greatest likelihood of clearing most volume of stone through a single puncture due to the favorable lie of the kidney. Using an upper pole puncture, the upper and renal pelvis stone burden can be cleared with a rigid scope; and most lower calyces can also be accessed with a rigid scope with minimal torque. A flexible nephroscope may then be used to clear the remaining stone burden, unless it is too large. In this

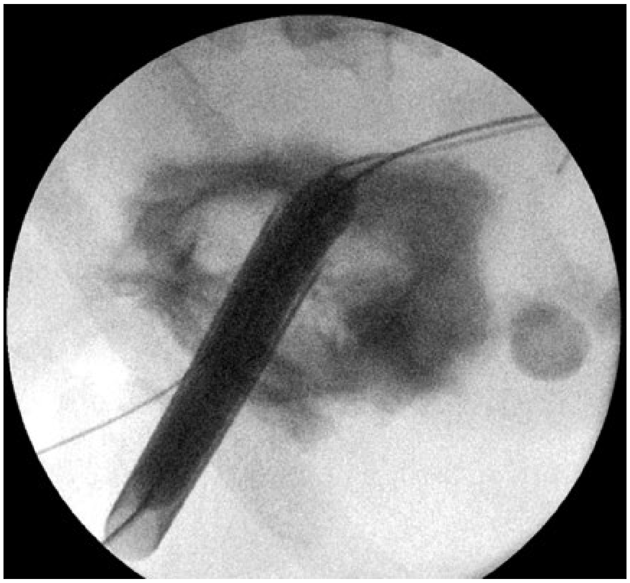

Figure 25.4 Balloon dilatation of the nephrostomy tract with subsequent advancement of the working tract (Ultraxx nephrostomy balloon set, Cook Medical). Dye is placed in the balloon to ensure no "waist" is seen, which would indicate need for further dilation.

case, second wires should be dilated for large mid-calyceal stones or inaccessible large lower calyceal stones.

Although studies have shown that multiple-tract access does not lead to more severe reduction in renal function compared to single tract access, multiple-tract access has been shown to lead to higher complication rates [23]. Nonetheless, as seen in Figure 25.1, collecting system anatomy and stone complexity often dictate a need for placement of further tracts.

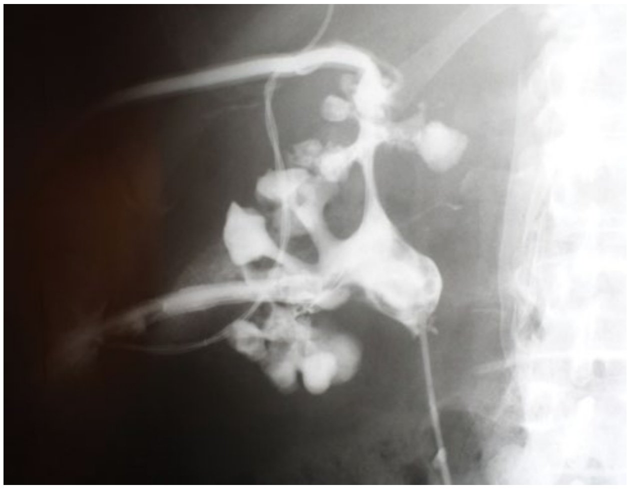

Figure 25.5 Two-tract puncture of the collecting system for treatment of a complex staghorn calculus, with initial dilatation of the upper pole tract, followed by the lower pole tract.

When the need for multiple tracts is anticipated, it is often best to insert multiple wires (such as in an upper, mid, and lower posterior calyx) prior to dilating the first tract when visualization of the collecting system is optimal. Once the wires are in place and secure, the first tract can be dilated (usually the upper tract for staghorn calculi), with dilation of the other tracts performed later in the case as needed (Figure 25.5). The alternative is to obtain multiple radiologist-placed accesses. When working with multiple tracts it is of utmost importance to try to obtain end-on calyceal puncture, as the procedure may be long and bleeding can be problematic. One is also more likely to torque to reach all areas of the kidney; thus careful selection and angulation of the tract is important (Figure 25.6).

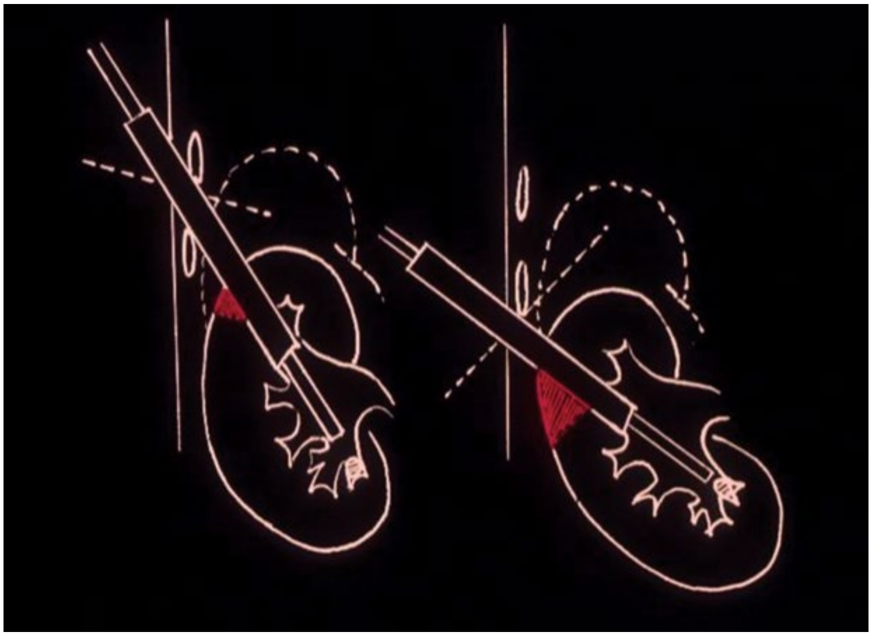

Figure 25.6 Excessive torque on the rigid nephroscope while looking down the axis of kidney can traumatize the renal parenchyma and infundibulum, resulting in bleeding.

## Stone fragmentation and removal

Devices for accessing and treating stone fragments should be used as deemed necessary to ensure complete stone-free status (including clearance of sand) particularly for struvite stones.

Tools for intracorporeal lithotripsy during PCNL include ultrasonic, pneumatic, or ballistic lithotripters, or combinations thereof. The LithoClast™ Master/Select with Vario Handpiece (Boston Scientific, Marlborough, MA, USA), for example, is a combined pneumatic and ultrasonic lithotrite which can be used independently, or in combination, for more efficient and faster stone clearance. Hand-held, standalone, pneumatic lithotripters (such as the Stonebreaker™, Cook Medical) can deliver up to 29 bars of pressure at the tip of the probe, allowing for effective treatment of very hard stones. Lithotripsy through flexible nephroscopes is limited to laser fragmentation, the holmium:YAG laser being the most effective.

Instruments for capturing, repositioning, and removing renal stones via flexible nephroscopy include tip or tipless nitinol baskets (e.g. ACMI Sur-Catch®, Bard Dimension®, Cook NCircle®), four-wire or multiwire baskets. These have no interference, or limited interference, with scope deflection. In addition, tools for removal of larger stone fragments via graspers though rigid nephroscopes include the three-prong grasper (Captura®, Cook Medical) and percutaneous nitinol baskets (Perc NCircle®, Cook Medical).

At our center, we most commonly begin with a trial of ultrasonic lithotripsy through a rigid nephroscope should the stone be easily accessible with minimal torque. Larger stone fragments are removed with a three-prong grasper or percutaneous nitinol basket through the sheath. Stone samples are sent for both stone analysis and culture and sensitivity. If the stone is too hard to fragment via ultrasonic lithotripsy, a hand-held pneumatic lithotripter is employed. Stones inaccessible via rigid nephroscopy are visualized with flexible nephroscopy, basketed, and removed, or repositioned in a calyx with more favorable angulation for treatment via laser lithotripsy.

## Exit strategies

The goals of drainage following PCNL are to ensure adequate urine drainage, minimize bleeding, and provide re-entry access to the collecting system when needed. Options include: nephrostomy tubes (pigtail, cope loop, Foley or Councill or Malecot catheters), re-entry tubes, nephroureterostomy tubes, ureteral catheters, and ureteric stents (tethered or untethered).

Traditional large-caliber tubes (Malecot, Councill, Foley, re-entry tubes) have been standard for post-PCNL drainage for many years. Their benefits include preservation of the tract for second-look procedures, as well as possible improved urinary drainage and hemostasis. However, these tubes can be painful and result in prolonged urinary drainage from the flank post removal. In addition, they require a nephrostogram prior to removal. Alternatively, smaller tubes, such as 10–12 Fr nephrostomy tubes maintain access to the kidney, while reducing patient discomfort. AUA guidelines recommend that in patients undergoing uncomplicated PCNL, who are presumed stone-free, placement of a nephrostomy tube is optional (conditional recommendation, evidence level grade C) [5, 6].

"Tubeless" PCNL has gained popularity over the last decade, and has been shown to be safe and effective [24]. This form of urinary drainage is not completely tubeless, as the name suggests. Rather, urinary drainage is established via a ureteric stent (tethered or untethered) or via a 5 Fr ureteral catheter without a nephrostomy tube. The advantages of "tubeless" (more accurately "nephrostomy-less") PCNL include less pain and internal urinary drainage. The disadvantages include lack of access for second-look procedures, need for cystoscopy for removal of untethered stents, and stent related symptoms. Many studies have documented additional advantages of "tubeless PCNL" including less narcotic use, shorter hospital stay, and faster resumption of postoperative activities [24]. "Tubeless" PCNL should, however, be reserved for uncomplicated procedures with no need for a second look, no major collecting system perforation, and no significant bleeding from the tract upon sheath removal. For patients with complex staghorn stones and particularly with infection stones, the "tubeless" approach is often less advisable and postoperative drainage with either a nephrostomy tube, nephroureterostomy tube, or nephrostomy tube and ureteric stent are preferable.

"Totally tubeless" PCNL has also been described wherein no form of drainage tube is left at the end of the procedure. On some occasions a safety open-ended ureteric catheter is left for 24 hours, then removed prior to the patient's discharge [25]. The advantages again include less pain, no external drainage, and no need for delayed tube removal. There are many disadvantages, however, including: no access preservation, no drainage, and a higher rate of reintervention (such as stent insertion). This exit strategy is best suited for simple PCNL procedures, and not advised for the management of more complex staghorn stones, particularly infected stones.

At our center, we place a tethered ureteric stent retrogradely at the completion of PCNL. The stent is removed in clinic one week post operatively upon completion of postoperative imaging (noncontrast CT scan and/or kidney–ureter–bladder X-ray) to confirm stone-free status. External nephrostomy tube drainage is reserved for significant bleeding, large collecting system perforations, long procedure, and/or multiple tracts, or when a stent cannot be placed.

A compromise to "tubed" and "tubeless" procedures is the placement of a nephroureterostomy tube. Initially, this can be left open, acting as a nephrostomy tube. Twenty-four hours later it can be clamped, acting as a ureteric stent. It can then be removed on an outpatient basis once edema has settled. The advantages of nephroureterostomy tubes include: less pain than large-bore tubes, options of internal and external urinary drainage, maintenance of tract access to kidney, ease of management, and no need for a secondary procedure or nephrostogram for removal. However, the stent component of the tube may still cause irritation. At our center, we prefer to leave a nephorureterostomy tube for complex intraoperative cases, such as those complicated by a small perforation, patients with urinary diversion, or patients at risk for postoperative sepsis (for example spina bifida, struvite stones) since it can provide maximal internal and external urinary drainage.

## Tips and tricks

Performing complex PCNL has a steep learning curve, particularly when obtaining one's own access. Some of the tips and tricks we have found helpful are listed here:

- If contrast is lost from a posterior calyx with the patient in the prone position, a small volume of air can be injected retrogradely via the occlusion balloon catheter, thus obtaining an air nephrogram to aid with calyx localization and puncture.
- If puncturing directly onto stone, it is important to push the needle "into" the stone, increasing the chance that the wire will be advanced into the collecting system rather than outside.
- It is often difficult to advance the working or safety wires down the ureter, particularly for staghorn calculi (although this is usually easiest to achieve from an upper pole puncture). In this case, excess wire should be curled within the renal pelvis or within a dilated calyx.
- In our experience, balloon dilatation of the nephrostomy tract is preferred, should resources allow. However, if metal telescoping dilators are used, additional care must be taken to ensure these are not over-advanced, as significant perforations can occur.
- Repeated use of the nephrostomy balloon for multiple tracts may fail and require a second balloon.
- The working sheath should always be used with the tip just within the collecting system. This tamponades venous bleeding, improves visibility, reduces fluid extravasation, and lessens the chance of hydrothorax with a supracostal approach. Just after placement of the sheath, position can be checked with a zero-degree rigid urethroscope to maximize irrigation flow and forward visualization. If short of the collecting system, further balloon dilatation over the working wire can be performed, and the sheath can be advanced further over the balloon.
- The nephrostomy tract should be placed in line with the axis of the kidney and the path of the infundibulum, where possible. This means that the C-arm should be angled "down" to the upper pole or "up" to the lower pole when puncturing with the bullseye technique (Figure 25.7). It is important to avoid a superiorly angled tract towards the upper pole, with a puncture below the 12th rib. Excessive torque on the rigid nephroscope while looking down the axis of kidney may split the parenchyma or may traumatize the upper pole infundibulum, resulting in bleeding. In this situation, residual stones should be treated with flexible nephroscopy and laser lithotripsy or via placement of a second tract.
- A ureteral access sheath, placed instead of the ureteral occlusion balloon, can be used to retrogradely reposition stones from inaccessible calyces with intraoperative retrograde ureteroscopy.
- For complex cases, the pros and cons of a long single session versus staged procedures must be considered.
- Completion of flexible nephroscopy and fluoroscopy prior to insertion of a stent or nephroureterostomy

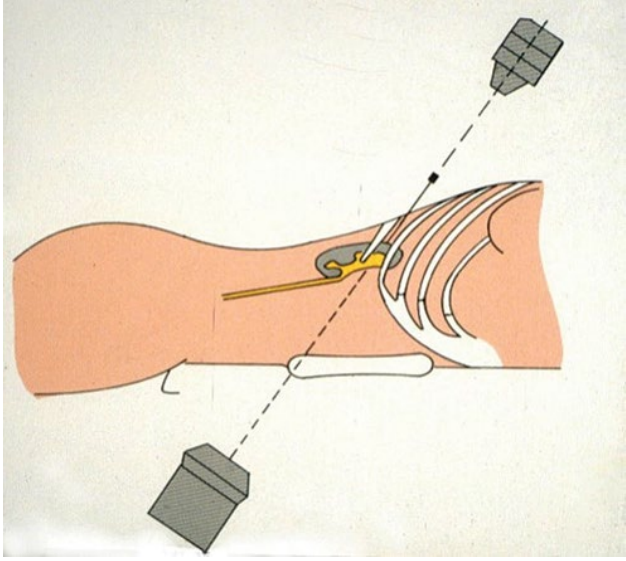

**Figure 25.7** The nephrostomy tract should be placed in line with the axis of the kidney and the path of the infundibulum, where possible. This means that the C-arm should be angled "down" to the upper pole when puncturing with the bullseye technique.

tube is essential for identifying any residual stone fragments. This practice is supported by the AUA guidelines (strong recommendation, evidence level grade B) [5, 6].

- At the end of the procedure, the C-arm can be used to perform fluoroscopy of the chest, ruling our hydrothorax or pneumothorax. If noted, a chest tube (or simple chest drain) can then be placed at the conclusion of the procedure, if deemed necessary.

## Complications

Complications of PCNL are not unique to PCNL for staghorn calculi and include bleeding and need for transfusion, perforation of the collecting system, adjacent organ injury, pleural complications (including hydrothorax, pneumothorax, and hemothorax), sepsis, nerve injury, and loss of nephrostomy drainage.

Transfusion rates have traditionally been reported to be as high as 26% [26]. Although recent series quote these to be much lower, at approximately 1–2% [27, 28]. Medications that may affect platelet function or coagulation must be identified and discontinued for an appropriate period prior to surgery. The most important strategy for minimizing bleeding during PCNL is careful planning and appropriate calyceal selection, with good endoscopic technique to avoid excessive torque on the kidney and large collecting system perforations.

Options for management of excessive bleeding during or immediately post PCNL include aborting the procedure and applying manual pressure on tract site, ensuring adequate drainage and access, temporarily clamping the nephrostomy tube, use of a tamponade balloon, administration of FLOSEAL (Baxter Healthcare, Deerfield, IL, USA) to the nephrostomy tract [29], angioembolization, or cryotherapy to the tract [30]. If the bleed is small and self-limited, a period of observation is reasonable.

Small perforations of the collecting system are not uncommon and usually seal within 48 hours with urinary drainage. Larger perforations of the renal pelvis are usually sustained due to over-advancement of rigid dilators, or the access sheath, or perforation during stone fragmentation. These can be managed with nephrostomy drainage for 7–10 days, and completion of a nephrostogram to document lack of extravasation prior to removal.

Adjacent organ injury to the spleen, liver, colon, and duodenum are extremely rare and can be avoided with patient positioning, correct surgical technique, and careful review of anatomical abnormalities on preoperative imaging. Lumbar nerve damage from too medial an access can also be sustained during PCNL, although this is exceedingly rare.

Intrathoracic complications have been reported at 1–3% [31, 32], and are substantially higher for supra-11th rib punctures. They can be managed conservatively, if small, or may require external tube drainage.

Urosepsis is not an uncommon complication of PCNL, particularly for struvite calculi. Should purulent urine be encountered during endoscopic intervention, the procedure should be aborted, and appropriate drainage and antibiotic therapy should be initiated [5, 6]. To mitigate risks, preoperative urine cultures should be obtained in all patients, and sensitivity-based treatment initiated in those with positive results. Studies have shown that antibiotic prophylaxis in patients undergoing non-extracorporeal shock-wave lithotripsy (ESWL) stone manipulation procedures reduces the risk of postprocedural UTI [32–34]. Periprocedural antibiotics should, therefore, be used in all patients undergoing PCNL. The choice of specific agent should be based, in part, on the local epidemiology of drug resistance in potential uropathogens [33]. Lastly, stone cultures, performed at the time of PCNL, can often better guide the choice of antibiotic post operatively, particularly in symptomatic patients with negative or mixed-growth urine cultures.

## Management of residual calculi

Akman and colleagues demonstrated that >60% of patients with residual stones after PCNL require second intervention [35]. Options for treatment of residual calculi include: SWL, ureteroscopy, repeat PCNL, or observation. Mechanical percussion and inversion is a good nonsurgical option for eliminating lower calyceal fragments, and has been shown to have a substantially higher stone-free rate than observation, with no adverse events [36].

## Conclusions

PCNL for staghorn calculi can be technically challenging, even in the hands of experienced surgeons. Careful preoperative workup and detailed and thoughtful review of preoperative and intraoperative imaging are essential components of successful PCNL. Although numerous innovations to the surgical technique and tools have been introduced, surgeon experience remains of paramount importance, particularly in the performance of complex percutaneous nephrolithotomy.

## Introduction

Intracorporeal lithotripsy involves the fragmentation and extraction of stone fragments during percutaneous nephrolithotomy (PCNL), cystolitholopaxy, and ureteroscopy. The diversity of stone location, size, and composition necessitates the employment of an armamentarium of both nimble and powerful lithotripters.

In complex stone cases, it is reasonable for a surgeon to use a variety of lithotripter devices to effectively clear a patient's stone burden, and therefore it is critical he or she is aware of the strengths and weaknesses of each device. There are four main varieties of lithotripters available for clinical practice: electrohydraulic lithotripsy (EHL), laser lithotripsy, ultrasonic, and pneumatic or ballistic lithotripsy. In this chapter, we discuss the mechanics and surgical technique necessary for the proper use of these instruments and review their specific advantages and disadvantages.

## Electrohydraulic lithotripsy

EHL was the first method designed for intracorporeal use. It was invented at the University of Kiev in 1955 by an engineer named Yutkin [1]. In 1985, EHL was applied to the treatment of ureteral stones after a 5 Fr probe was developed. The modality was deemed safe, as in the initial evaluation of the device there were no long-term complications noted [2]. Later improvements encompassed the development of even finer, even more flexible equipment that could be used in flexible ureteroscopy, first reported in 1988 [3].

### Mechanism of action

The working component of the EHL probe comprises a pair of concentric electrodes maintained at different voltages and separated by an insulating layer. When a current is applied that is strong enough to overcome the insulating gap between the electrodes, an electric spark is created, just like in a spark plug. With the spark procurement, a plasma channel is formed that vaporizes the water around the electrode. The explosive expansion of the plasma creates a hydraulic shock wave that then leads to the formation of a cavitation bubble (Figure 26.1). At a distance of approximately 1 mm from the surface of the stone, the cavitation bubble collapses in a symmetric fashion causing a secondary shock wave that assists in stone fragmentation. A third shock wave develops from the rebound of the cavitation bubble [4, 5].

In intracorporeal use of EHL, in contrast to extracorporeal shock-wave lithotripsy (ESWL), the shock wave is not focused; therefore, the stone must be placed directly in the path of the shock wave that is generated. Concerns over probe safety and the use of the appropriate settings have been closely examined. The original larger probes (9 Fr) have been replaced by probes smaller than 5 Fr. Although the larger ones are more durable, the smaller probes are no less efficient at fragmenting stones and have the additional advantage of flexibility [6].

### Technique

In ureteroscopic procedures, smaller probes measuring 1.6–1.9 Fr are used. Optimally, the probe should be extended at a distance of 2–5 mm from the distal tip of the endoscope. This protects the optics of the scope from damage during probe use. The targeted stone should be clearly visible before it is engaged. The probe is positioned 1 mm from the stone surface to maximize the shock-wave energy transmission to the stone. Energy settings should begin with low voltages between 50 and 60 V and titrated up as needed to fragment the stone. The stone fragments should be small enough to be

retrieved with a grasper or basket device. Pulverization of the fragments to a size less than 2 mm is not recommended, as it can cause unintended damage to the surrounding urothelium [7].

### Advantages and disadvantages

EHL is shown to effectively fragment about 90% of ureteral stones [8]. In a series involving 207 renal and ureteral stones treated with EHL, 90.3% of stones were successfully fragmented and 82.1% of patients were stone free at 20 months follow-up. The characteristics of the stone surface strongly contribute to the efficacy of EHL fragmentation; rough stone surfaces fragment more easily than smooth ones [9]. It has also been suggested that EHL is less efficient in fragmenting uric acid stones compared to calcium oxalate monohydrate varieties [10]. These stone-free rates are in fact inferior to those of other lithotripters. In stones larger than 1.5 cm, Techman [11] reports stone clearance rates of 67% using EHL, a figure significantly higher than that for the holmium:YAG lithotripter.

Like the holmium:YAG laser, EHL is incredibly flexible. The 1.9 Fr probe can be utilized throughout the upper urinary tract with either rigid or flexible ureteroscopy. It has been suggested that the 1.6 Fr EHL probe is even more flexible than a 200 μm laser fiber [12]. The holmium:YAG laser is the only probe that offers a comparable size and flexibility advantage [13].

In terms of cost, EHL is also the cheapest lithotripter available. The cost of a generator is approximately US$1200 and each disposable probe is US$200 [14]. Usually one or two probes are used in each case, unless a harder stone (e.g. calcium oxalate monohydrate) is encountered.

A major concern with the use of an EHL probe is the damage it may cause to the collecting system. Because, unlike in ESWL, the energy generated by the probe is not focused, the cavitation bubble, can expand and perforate the ureter or renal pelvis. When energy levels greater than 1300 mJ are used, the cavitation bubble expands to over 1.5 cm and places the system at a higher risk of perforation. Thus, when treating a harder stone the risk of perforation is greater. Moreover, given that the expanded cavitation bubble is the inciting event causing injury, the probe need not be in direct contact with the tissue to cause damage [4]. Using a rabbit model, Bhatta et al. reported that an unshielded EHL probe can perforate the bladder with just two pulses of direct contact with the tissue, compared to the six needed by a laser [15]. Even the use of smaller probes carries a risk of perforation. *In vitro* models suggest that placing a 3 Fr probe 0.5 cm from a ureteral wall will induce perforation after an average of 24 pulses from an EHL probe [16]. In clinical practice, the incidence of perforation ranges from 2.9% [10] to 17.6% [17]. Risk factors that increase the likelihood of perforation include stone impaction and poor visualization caused by mucosal edema or hemorrhage [17].

An additional concern with the EHL probe is the extent of retrograde propulsion of stone fragments it causes. Yang and Hong [18] noted in their series of 43 patients with a single mid or proximal ureteral stone that 14% of patients initially treated with an EHL probe required a secondary ESWL to manage stone fragments that were scattered in the kidney. Moreover, the EHL probe tends to fracture stone into larger fragments, especially those greater than 15 mm in size, requiring additional manipulation and travel up and down the ureter [11].

## Laser lithotripsy

Lasers are devices that emit light through stimulated emission of electromagnetic radiation using optical amplification. The term “laser” is itself an acronym for light amplification by stimulated emission of radiation. The energy from a laser is formed when an energy source stimulates an atom. Its electrons are then elevated to an excited metastable orbit. When the electrons relax and return to their natural states, they emit energy in the form of a photon, a discrete amount of light energy. Unlike other devices that emit natural light, lasers uniquely emit photons that are monochromatic (all of the same wavelength), coherent (all in the same phase), and collimated (travelling in courses parallel to one another) [19]. These properties of laser light allow it deliver significant amount of energy in a very concentrated manner.

Different varieties of lasers are named based on the substance that is excited to produce the focused light energy. The coumarin laser was the first clinically utilized pulsed dye laser, employing green coumarin dye as the liquid laser medium [20]. The laser has a reported 80–95% rate of success in fragmenting stones [21]. Despite the major advancement this laser provided, there were drawbacks to the device. First, coumarin is an extremely toxic agent and required careful handling and disposal. Second, the laser was much less effective in fragmenting hard, dense stones, namely calcium oxalate monohydrate and cysteine varieties, limiting its applicability and efficacy. Third, the device and its disposable parts impose a significant upfront cost [21].

### Holmium:YAG laser

The holmium:YAG laser is a modern, widely used iteration of the laser lithotrite and is based on a solid-state laser system that improves on the deficiencies of the pulsed dye laser. The device emits light at a wavelength of 2140 nm and exhibits a pulse duration of 250–350 μs, much longer than the short pulsed dye lasers. This laser's mechanism of action in stone fragmentation appears to be mainly thermal. The laser energy superheats the water and forms a microscopic cavitation bubble at the end of the fiber that then implodes rapidly, creating the shock wave that fragments the stone [22]. The holmium laser energy is also highly absorbed by water, and as a result much of it diffuses into the surrounding tissue. This provides a superficial narrow range for resection or ablation of 0.5–1 mm [23]. As a result, accurate placement of the fiber onto the stone is the predominant method of avoiding urothelial injury. With this system, all stones are fragmented with a success rate of approximately 90% [24].

### Technique

When operating the holmium laser, the fiber should be placed directly on the stone surface before the laser is engaged. The target stone should always be kept under direct vision to minimize the risk of perforation or injury to the collecting system. The laser causes minute stone fragments and debris to develop, obstructing the visual field. Care should be taken to irrigate gently during the lithotripsy process as the flow of fluid can displace the stone, moving it out of reach of the laser [25]. In addition, aiming the laser at either a wire or basket device should be avoided. The holmium laser can easily cut metal, creating iatrogenic debris [26, 27]. The fiber should be extended about 2 mm from the tip of the endoscope in order to prevent damage to the lens, optical system, or working channel of the endoscope. For maximally efficient stone fragmentation, the surgeon should aim to vaporize the stone. To achieve this, the fiber is swept over the broad leading edge of the stone as if painting it. Attempts should be made to avoid drilling deep into the stone as this causes fracturing. In addition, drilling increases the risk of fracturing the tip of the laser as well as unwittingly drilling past the stone and damaging the urothelium [28].

The holmium laser is available in four different sizes: 200, 365, 500, and 1000 μm diameters. The fibers can be either end-firing or side-firing, and only the smaller two sizes, 200 and 365 μm fibers, are pliable enough to used in flexible ureteroscopy. Most commonly, the end-firing fibers are used; they are the standard when performing ureteroscopic lithotripsy. The efficiency with which the holmium laser fragments stones corresponds with the energy density produced, a factor reliant on the pulse energy and the fiber diameter [29]. Energy density correlates inversely with laser fiber diameter: the smaller the fiber, the greater the energy density produced [30]. At the beginning of stone fragmentation, a low pulse energy (i.e. 0.6 J) and pulse rate (6 Hz) are recommended to decrease the amount of stone retropulsion and to maximize the margin of safety of the lithotripter. Increasing the pulse frequency (max 15 Hz) is preferable to increasing the pulse energy (max 1.2 J) when aiming to increase the speed of fragmentation [31].

### Advantages and disadvantages

The benefits of the holmium laser are centered on its safety, efficacy, and versatility. Holium laser energy is quickly dispersed in water, limiting its depth of penetration to ~1 mm [32, 33]. The holmium laser can be active 0.5 mm from the ureteral wall with minimal adverse effects. In a porcine mode, the holmium laser was unable to perforate the collecting system when held 2 mm from the ureteral wall, even at the highest power settings [16]. In direct contact with tissue, however, the holmium laser can cause damage. In one study, it was found that just 2 seconds of targeted contact of the holmium laser with ureteral tissue was enough to cause perforation [23].

The holmium laser is also able to fragment stones regardless of their composition, with success rates ranging from 91% to 100% and stone-free rates following ureteroscopy reported from 87% to 100% [34–40]. The success rates with use of the holmium laser depend on the location of the calculus within the collecting system. In a series of 598 patients with an overall success rate of 97% with laser use, location of the stone within the renal, proximal, middle, or distal ureteral segments yielded stone-free rates of 84%, 97%, 100%, and 98%, respectively [40]. The holmium laser can be employed in both regtrograde and anterograde approaches to calculi. Success rates in PCNL after a single-stage procedure have ranged from

61.4% to 89% [41–43]. Malik et al. have reported that in treating a single 2.5 cm stone via PCNL, the holmium laser provided complication and stone-free rates comparable to those from a pneumatic LithoClast. However, the operative time was significantly longer in patients treated with the laser [44].

Further benefits of the holmium laser are its production of smaller stone fragments as compared to other lithotripters. The finer debris is easily irrigated out of the collection system, thereby reducing the need to manually extract residual fragments with graspers or a basket [45]. Among the different laser fiber sizes, the 200 μm causes the least amount of retropulsion [46].

Disadvantages of the holmium laser include its initial high upfront cost. This is mitigated by its versatility in treating not just stones but a variety of other urologic conditions, which helps offset the initial cost of the device. In addition, the larger 365 and 500 μm fibers exhibit a non-negligible degree of retropulsion [41]. Currently the smallest fibers inhibit the deflection of a flexible ureteroscope by about 20°. Smaller or more pliable alternatives would improve the ability to optimally reach and fragment stones in calyces difficult to traverse. In addition, if the fiber breaks within the working channel, the scope is completely damaged and cannot be salvaged. Increased durability of the fibers may reduce the incidence of these events. Moreover, a theoretical concern of using the holmium laser fiber to treat uric acid stones is the production of cyanide that could cause toxicity. Currently there is no evidence to suggest from clinical experience that the holmium laser is a source of cyanide toxicity [45].

## Ballistic lithotripsy

The first ballistic lithotrite was a Swiss device introduced in the early 1990s named the "LithoClast." This device uses compressed air to propel a metal projectile that is central to its fragmentation mechanism [47]. In contrast, the electric-powered electrokinetic lithotripter houses an electric coil that generates an electromagnetic field that vibrates the probe. Both probes are effective and safe lithotrites with no difference in fragmentation, retropulsion rates, or safety [48, 49].

### Mechanism of action

Ballistic lithotripsy uses the harnessed energy from the motion of a projectile that comes into contact with another object, transferring its ballistic energy. The stimulation of the projectile initially can come from a variety of sources, and once the ballistic energy is transferred from the projectile to a probe, that energy is in turn transferred to the other object with which the lithotripter is in contact, like a jackhammer (Figure 26.2). Objects that receive the probe's energy that are flexible, such as tissue, absorb the momentum, whereas rigid objects that are targeted, such as a stone, are fragmented. The metal projectile in the LithoClast is propelled at a rate of 12 cycles every second, caused by controlled blasts of compressed air at 3 atm [50]. In contrast, the electrokinetic lithotripter operates at a higher frequency of 15–30 cycles per second through stimulation by the generator's electromagnetic field [48].

### Technique

Like all lithotripters, the ballistic probe should be engaged only when both the probe and the stone are in clear view. The probe should be brought into direct contact with the stone before using the pedal to activate the device. Optimally, the stone should be placed in a location where it is not able to move. This is not a challenge in the kidney or the bladder but is more difficult in the ureter. The stones may be fixed with a basket or occlusion balloon if necessary. The end-goal with this device should be to break the stone into fragments <2 mm and small enough to pass spontaneously. Realistically, however, using ballistic probes, larger fragments are generated that will require manual extraction with a basket or graspers.

### Advantages and disadvantages

Ballistic lithotrites are effective in fragmenting urinary stones and exhibit a wide margin of safety. Successful

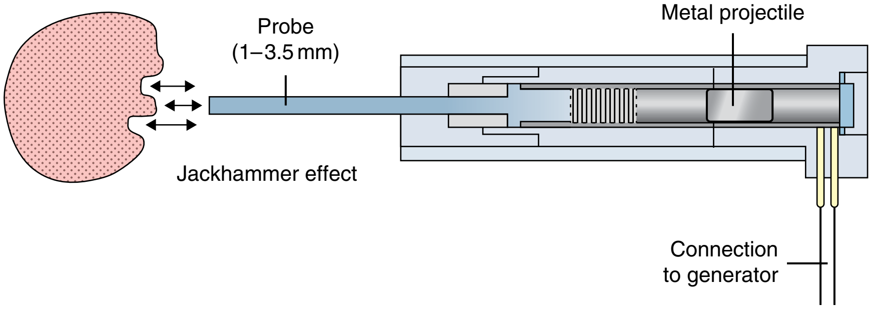

**Figure 26.2** Schematic illustration of a ballistic lithotripter hand-piece mechanism. An oscillating pellet provides ballistic energy to the probe, resulting in a jackhammer-like effect on calculi. *Source:* Matlaga BR and Lingeman JE. *Campbell Walsh Urology*, 10e, 1382–1386. London: Elsevier, 2012. Reproduced with permission of Elsevier.

fragmentation is reported to be between 73% and 100%, a rate that is comparable to that for EHL probes [17, 51–56]. The reported rates of lower efficacy are from studies that have identified deficiencies in the LithoClast that compromise its performance. Knispel et al. [53] noted that when the probe is exercised out of a working channel of a semirigid 6.9 Fr ureteroscope, performance is compromised. These findings are echoed by Zhu et al. [57] who found that the 0.89 mm flexible probe in a flexible ureteroscope was deflected more than 24°. In addition, bowing of the probe is found to reduce the power in ballistic devices [58]. The areas in which ballistic lithotripters are most effective are those in which the stone can be cornered by a rigid device, lending itself better to PCNL and cystolitholapaxy. In these procedure, the stone burden is greater and there is potential to encounter very hard stones, both characteristics that ballistic lithotripters are optimally designed to address. In contrast, it would be disadvantageous to use ballistic lithotripters for ureteral stones or renal stones approached in a retrograde fashion. In these locations and procedures, other modalities provide superior stone fragmentation and clearance rates [59].

Compared to other lithotripters, ballistic devices carry a low risk of perforation. In animal model studies, the ballistic probe was compared to EHL, ultrasonic, and laser lithotripters. Results of these trial revealed that despite direct contact of the probes with bladder and ureteral tissue, ballistic and ultrasound probes did not cause any perforation. On examining the histology of the tissues, it was noted that the LithoClast at most caused partial abrasions of the urothelium [60]. These findings are corroborated by Santa-Cruz et al. who showed that despite 6 minutes of direct continuous contact of a ballistic probe to porcine tissue, no ureteral perforation was noted [16].

From a cost perspective, ballistic probes are an economical option. Although the upfront cost of a generator at around US$30,000 is high, the probe itself costs only US$150 and is reusable [17].

The disadvantages of ballistic lithotrites include the requirement of a straight working channel to be effective. The technology works best in a rigid-probe model, meaning that, as previously stated, its use is limited in flexible endoscopy. These devices are also prone to inducing high rates of stone retropulsion of around 17%, especially in ureteral stones. This is in part attributed to the difficulty in trapping a stone in the ureter [50]. Retropulsion is also propagated because ballistic probes are solid probes that lack a suction channel. The newer LithoVac accompanying suction device works to mitigate that problem. It provides suction to facilitate the evacuation of small <2 mm fragments during lithotripsy when the probe is in place. When the LithoClast is removed from the channel, fragments as large as 3.5 mm can be evacuated as well [61]. Reports on using an 0.8 mm ballistic lithotripter through a 4.8 Fr hollow LithoVac device in a series of 21 patients gave a 95% stone-free rate at three month follow-up. In addition, observationally, the LithoVac was helpful in reducing stone migration and maintaining good visualization [52].

Ballistic lithotripters also usually produce fragments that are larger than 4 mm. Residual stones of this size are large enough to cause obstruction if left untreated [45]. However, fragmenting stones to sizes smaller than 4 mm is a distinct challenge with ballistic probes, especially within the ureter. As a result, additional manipulation is required, such as fetching fragments with a basket or grasper, to reduce the rate of repeat ureteroscopy after the initial procedure [62].

## Ultrasonic lithotripsy

The use of ultrasound vibrational energy to break renal calculi dates back to 1953 when the technique was described by Mulvaney [63]. Ultrasound employs acoustic waves of a frequency above the 20 kHz threshold, which is audible to the human ear. Since the 1950s the technology has matured to become a common and effective and safe means of lithotripsy, especially in treating intrarenal stones in PCNL.

### Mechanism of action

An electric current is used to excite a piezoceramic plate within the ultrasound transducer, causing it to resonate at a certain frequency between 23 and 25 kHz [64]. The vibrational energy of the transducer is transmitted to a hollow steel probe which in turn vibrates longitudinally and transversely (Figure 26.3). With the probe in direct contact with the stone, it stimulates the stone to resonate at a high frequency and fragment. When the probe is directed on the compliant tissues of the collecting system, minimal damage is sustained because tissue does not resonate [1]. The ultrasound probe is also connected to a suction device that is engaged intermittently only when the lithotripter is activated. The pressure is maintained between 60 and 80 cm $H_2O$ to optimize visualization, removal of debris, and irrigation.

The compositions and physical characteristics of stones have an effect of the ability of ultrasound to fragment them. Some stones, particularly harder ones such as calcium oxalate monohydrate, cysteine, and uric acid stones, are more difficult to fragment. However, the the size and surface characteristics of the stone appear to have a greater impact on the efficiency of fragmentation. Smaller, rougher stones are more rapidly fragmented, whereas smooth, larger ones pose more of a challenge [64, 65].

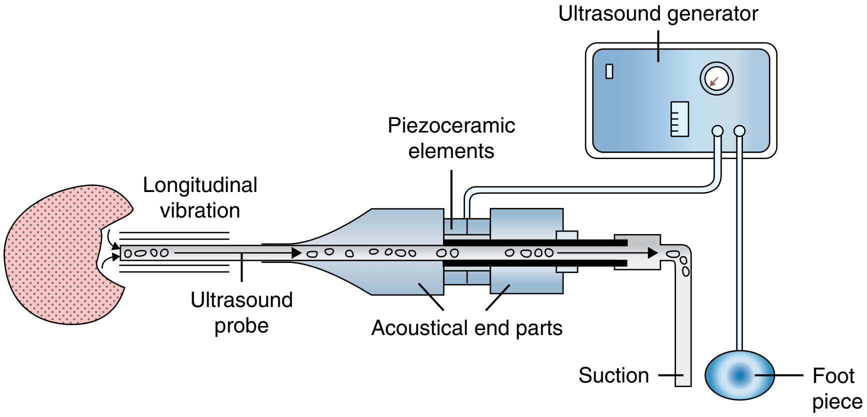

**Figure 26.3** Ultrasound lithotripsy generator and hand-piece. *Source:* Matlaga BR and Lingeman JE. *Campbell Walsh Urology*, 10e, 1382–1386. London: Elsevier, 2012. Reproduced with permission of Elsevier.

The probes are manufactured in sizes ranging from 2.5 Fr to 12 Fr. The larger probes contain a hollow channel through which suction is applied, while the smaller probes (2.5 Fr) are solid and therefore lack suction capabilities. The presence of the hollow channel is a major advantage for the probe. Moreover, the probes are rigid, and if they are torqued or bent during use, the most convex point is a source of energy loss as the vibrations are transformed to heat [65].

### Technique

In PCNL the stone should be pinned against the urothelium. Gentle pressure should be applied while the device is engaged to enhance fragmentation. The surgeons should, however, be mindful to refrain from the use of excessive force as there is a risk of pushing the stone or its fragments through the urothelium. Given the rigid nature of the ultrasound probes ultrasonic lithotripsy appears to be most effective in treating distal ureteral stones. Success rates for ultrasonic lithotripters in addressing proximal, middle, and distal ureteral stones have been reported at 91%, 94%, and 98%, respectively [66]. In ureteroscopic access, the ureter may also need to be dilated to allow the rigid ureteroscope to pass without difficulty. As with other lithotripters, the goal when using the ultrasound lithotripter is to pulverize the stone into small, manageable fragments that can pass spontaneously or be manually extracted during the procedure.

### Advantages and disadvantages

With larger caliber ultrasonic probes, a major advantage is the ability to fragment and remove the stone in tandem. In addition, studies have repeatedly shown that the percutaneous ultrasound treatment of renal stones is effective, with success rates of 84–100% [67, 68]. When the newest iteration of ultrasonic probe, the UreTron® (Med-Sonics, Erie, PA, USA), was compared with competing dual-probe combination lithotripters, it was found to be equally effective and more efficient in treating stones >2 cm. The UroTron gave the highest stone clearance rate compared with the alternative lithotripter cohort (51.9 $mm^2$/min vs. 35 $mm^2$/min, $P = 0.02$) without any differences in stone-free or complication rates [69]. Ultrasound probes are also exceedingly safe. Piergiovanni et al. discovered on a porcine model that perforation was not possible when applying ultrasonic probes on bladder and urothelial tissues without pressure [60]. The authors concluded that in terms of perforation, ultrasonic and pneumatic probes are safer than EHL probes and laser lithotripsy.

Once again, it is important to recognize that a disadvantage of this probe is its limited appeal in tackling ureteral stones. The technology can be used in semirigid ureteroscopes, but a relatively large 5 Fr working channel is needed to accommodate a 4.5 Fr hollow probe. In this setting, success rates have varied from 69% to 100% [70, 71]. Ureteroscopically, the best applications may be for large distal stones or in patients with steinstrasse.

## Combination ultrasonic and ballistic lithotripters

It is evident that both ultrasonic and ballistic lithotripsy have their advantages and disadvantages. Ultrasonic probes offer the suction and optimal irrigation to decrease the extent of stone retropulsion and clear debris and small stone fragments, but they are less effective in clearing dense, hard stones such as calcium oxalate monohydrate. Ballistic probes, on the other hand, outshine ultrasonic probes in this respect. They efficiently tackle hard or very large stones [59, 72], yet they lack the effective suction capabilities of their ultrasonic counterparts.

Thus, the LithoClast Ultra (Boston Scientific, Natick, MA, USA), which combines both ultrasonic and ballistic lithotripsy to optimize stone fragmentation and evacuation was developed. The probe has a hand-piece that incorporates control for the two separate units together. When activated together, the probe maximizes stone fragmention and evacuation capabilities. The first clinical test of the LithoClast Ultra by Haupt et al. in 2001 [73] showed that it was effective in removing renal and bladder stones in 15 patients.

Given the numerous lithotripter options, adding a combined device brings into question whether these devices are equally as or more efficacious in clearing stones than the single-mode devices. *In vitro* assessments were needed to determine the veracity of the manufacturers' claims. Kuo et al. [74] developed a hands-free mechanism to test the LithoClast Ultra. The probe is placed in an upright position and secured by the testing system, and a phantom gypsum stone is placed on top of the lithotripter and compressed with a 63.4 g weight. The aim of this study design is to determine the optimal time for the probe to completely penetrate through the cylindrical phantom stone. Results indicated that using a pneumatic frequency of 12 Hz and ultrasonic power of 100% the stone was penetrated in 9 seconds.

Clinically, the combination lithotripters also perform well. One series investigated 20 patients with symptomatic renal stones who were randomized to PCNL with either a combined lithotripter or standard ultrasonic lithotripsy. The combination device was far more efficient in clearing stones compared to the ultrasonic probe (21.1 seconds vs. 43.7 minutes), and exhibited a greater rate of stone clearance (39.5 vs. 16.8 $mm^2$/min) [75]. In another randomized trial with 30 patients, participants were again randomized to PCNL with either a combined lithotripter or ultrasonic lithotripsy. Here results indicated that both type of devices were equally effective in clearing stones in total (46% and 66%, $P = 0.26$), but once the patients were stratified based on stone composition, it became evident that the combined probe was more efficient in fragmenting harder stones [76].

Other examples of combined lithotripters include the CyberWand (Gyrus ACMI, Southborough, MA, USA), which utilizes a dual ultrasonic probe approach with two coaxial probes, one high and the other low frequency. The dual probes have a synergistic effect that improves on the efficiency of the single-probe ultrasonic probe while maintaining the suction and irrigation capabilities of a traditional single-probe ultrasonic device (see Video 26.1). One study utilized the hands-free *in vitro* testing method previously described by Kuo and associates to assess the stone penetration rate of the CyberWand, and determined that this device is able to completely penetrate the stone twice as fast as the LithoClast Ultra [77]. Clinically, however, results have not shown an appreciable advantage with this device. Krambeck et al. [78] performed a randomized trial in which patients were placed in an arm that tested the CyberWand and another using a traditional single ultrasonic probe. Patients with renal stones >2 cm were treated and no significant difference was found between time to clearance (15.8 minutes vs. 14.2 minutes), or stone-free rates (60% vs. 62.5%) after initial surgery when comparing the CyberWand to a single ultrasonic probe, respectively.

## Conclusions

When choosing a lithotripter to optimally manage genitourinary stones, the patient's anatomy, stone location, stone accessibility, and the planned surgical approach should all be considered. The current options provide the urologist with a number of effective probes to manage these stones, but it is incumbent on the surgeon to combine these factors with a deep understanding of the mechanics and knowledge of the strengths and weaknesses of each in deciding which one to use. The holmium laser is widely considered the most versatile, and it is the most extensively employed method for fragmenting stones ureteroendoscopically. Its flexibility and small-diameter fibers allow for stone management within the entire ureter and the intrarenal collecting system. In patients with significant stone burden undergoing PCNL, however, mechanical lithotripters (i.e. ultrasonic, ballistic, and combination devices) are most effective in safely and efficiently clearing large stone burdens. It is important to note that in a single case, multiple different lithotripsy modalities can be used to ensure complete clearance depending on the situation. Finally, combination devices and other new technologies are promising but require further investigation to ensure that they increase the effectiveness of single-probe systems.

## Introduction

Rupel and Brown reported on the first pediatric patient having a renal calculus removed via a nephrostomy tract in 1941 [1], but it was not until 1985 that Woodside et al. presented the earliest series of percutaneous nephrolithotomy (PCNL) in children [2]. In this study, seven patients aged 5–18 years old were treated successfully using adult-sized instruments and equipment. Over the years, the development of smaller nephroscopes and instruments, along with advancements in the form of more efficient energy sources, have resulted in PCNL replacing open surgery for treating both adults and children with large stone burdens, with PCNL monotherapy having stone-free rates approaching 90% [3–5]. Most recently (2015) Lee et al. found PCNL in pediatric patients to be safe and efficacious compared to a matched adult cohort, with similar rates of second-look nephroscopy, length of stay, and complications [6]. There was, however, a higher requirement for a second access tract in the pediatric cohort (15.4%) compared to adults (4.52%). The authors postulated that this was because the small access tracts used in the pediatric cohort made it more difficult to clear the stone burden and another tract was necessary in order to accomplish this without placing too much torque on the tract [6]. PCNL has even been performed successfully in children who have had previous PCNL or open pyelolithotomy, with stone-free rates of 79.17% and only 4.2% requiring blood transfusion [7].

### Indications

Although there are no absolute indications for PCNL in children over any other treatment modality by any current consensus, relative indications include a large stone burden (>2 cm) in the upper urinary tract, lower pole stones larger than 1 cm, an anatomic abnormality which impairs drainage and stone clearance, certain metabolic abnormalities such as cystinuria, or known struvite stone composition [8]. Proper diagnosis is essential as staghorn calculi may be confused with nephrocalcinosis, a condition most often managed nonsurgically [9]. The most recent American Urological Association (AUA) guidelines for treatment of stones in children recommend that PCNL and extracorporeal shock-wave lithotripsy (ESWL) are reasonable treatment options for total renal stone burdens larger than 2 cm. They also recommend that a low-dose, noncontrast computed tomography (CT) scan be obtained prior to PCNL (having the patient in the prone position during CT can be helpful for surgical planning). For patients with questionable function of the renal unit with stones, the panel recommends that a functional study such as a DMSA or MAG3 nuclear renal scan be performed to ascertain if alternative treatment (e.g. nephrectomy) is needed [10].

### Risks

PCNL carries many risks, such as failure to remove all stone fragments, bleeding either immediately post operative, requiring blood transfusion, or delayed renal hemorrhage (both of which may require angioembolization), urine leak requiring stent placement, injuries to adjacent organs (most commonly bowel), inadvertent entry into the chest cavity (pneumothorax, hemothorax, urothorax), and sepsis. A preoperative urine culture should be checked two to three weeks prior to surgery and treated if positive. Broad-spectrum intravenous antibiotics should always be given at the time of the procedure even if the cultures are negative. The AUA guidelines also recommend that a complete blood count including platelet count be obtained before PCNL [10].

## Pediatric concerns

Although PCNL has been shown to be safe and effective in the adult population, it is not as well established in pediatric populations. Historically, urologists were reluctant to perform this operation in children due to the concerns about parenchymal damage and subsequent insults to renal function from the large adult-size instruments. In the early days of PCNL, smaller/pediatric equipment did not exist. Figure 27.1 demonstrates how the smaller body types of children (Figure 27.1a) have less distance from collecting system to skin (along with total body surface area) than adult patients (Figure 27.1b). Major surgical complications such as bleeding and sepsis when there are fewer invasive options, along with increased radiation exposure from prolonged fluoroscopy, are other considerations that make pediatric providers hesitant to perform PCNL. In addition, there is increased potential for hypothermia along with its sequelae (e.g. coagulopathy) and hyponatremia (e.g. seizures, coma) due to prolonged exposure to irrigation. To decrease the risk of hypothermia, warm isotonic solutions should be used for irrigation, along with warming the operating room, proper draping, monitoring of body temperature throughout the case, and limiting operative times to less than 90 minutes. Warm saline should be used for irrigation whenever feasible, although this would have to be switched to warm water or glycine if an electrosurgical procedure is performed, despite the risk of dilutional hyponatremia.

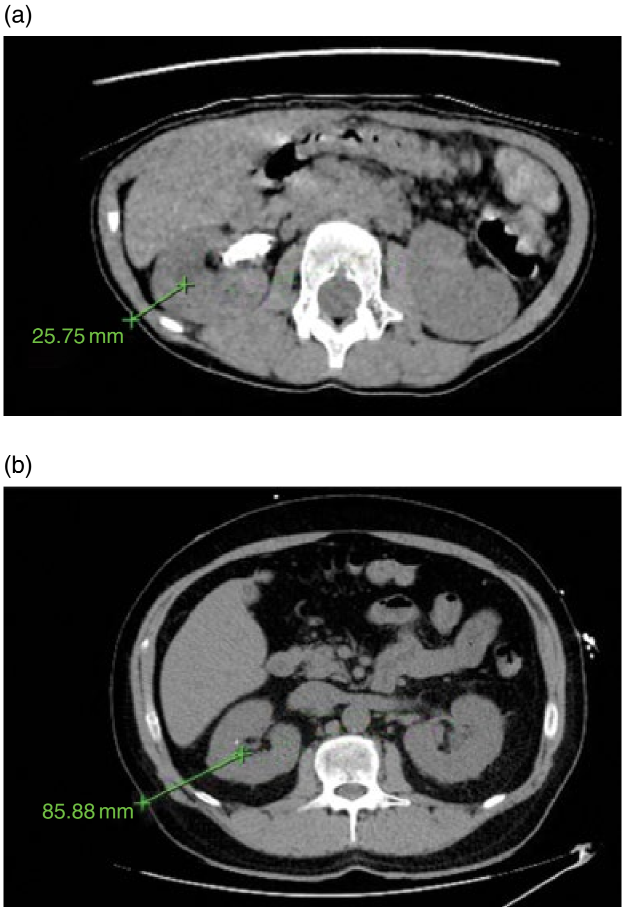

**Figure 27.1** (a) CT scan of a 9-year-old male showing a skin-to-collecting system distance of 2.5 cm, compared to (b) that of a 44-year-old woman with a skin-to-collecting system distance over three times longer (8.5 cm). This demonstrates how the spinal needle should not be inserted as deep during access in younger patients.

## Patient positioning

The procedure is almost always performed under general anesthesia. The patient is first placed in dorsal lithotomy position and an open-ended ureteral catheter is advanced to the level of the proximal ureter (Figure 27.2a). The ureteral catheter size chosen will vary depending on the size of the patient. Figure 27.3 shows the smaller sized ureteral catheters which can be used in children. In the smallest of children, a 3 Fr open-ended catheter is used. The ureteral catheter is left in place with the proximal end within the ureter, and a Foley catheter is placed alongside this for bladder drainage. The patient is then faced prone, with the flank elevated 30° for percutaneous access. Care must be taken to protect and cushion all body parts [11]. If the patient is large enough, they may be placed in the prone position initially with flexible cystoscopy used for ureteral catheterization. This modification obviates the need for repositioning and will aid in decreasing surgical and anesthesia time. Certain patients within the pediatric population who are prone to urinary stone disease offer a special set of challenges in performing PCNL. These patients include those who are wheelchair- or bed-bound, and patients with spina bifida. Patients with spina bifida can have existing spinal hardware which may restrict spinal mobility, impede percutaneous needle placement, and hinder radiographic imaging during the case.

In this patient population, latex-free catheters should be used. Many of these patients may also have limb contractures which makes positioning difficult, and care must be taken to place the extremities in the most comfortable position without excessive flexion and tension on the joints. The risk of pneumothorax is increased with scoliosis, kyphosis, or lordosis due to altered renal anatomy [12]. Patients who are paraplegic or quadriplegic have been shown to have worse outcomes after PCNL, as Danawala and Singh showed, with these patients being three times as likely to suffer a complication from the procedure than nonparaplegic/quadriplegic patients [13].

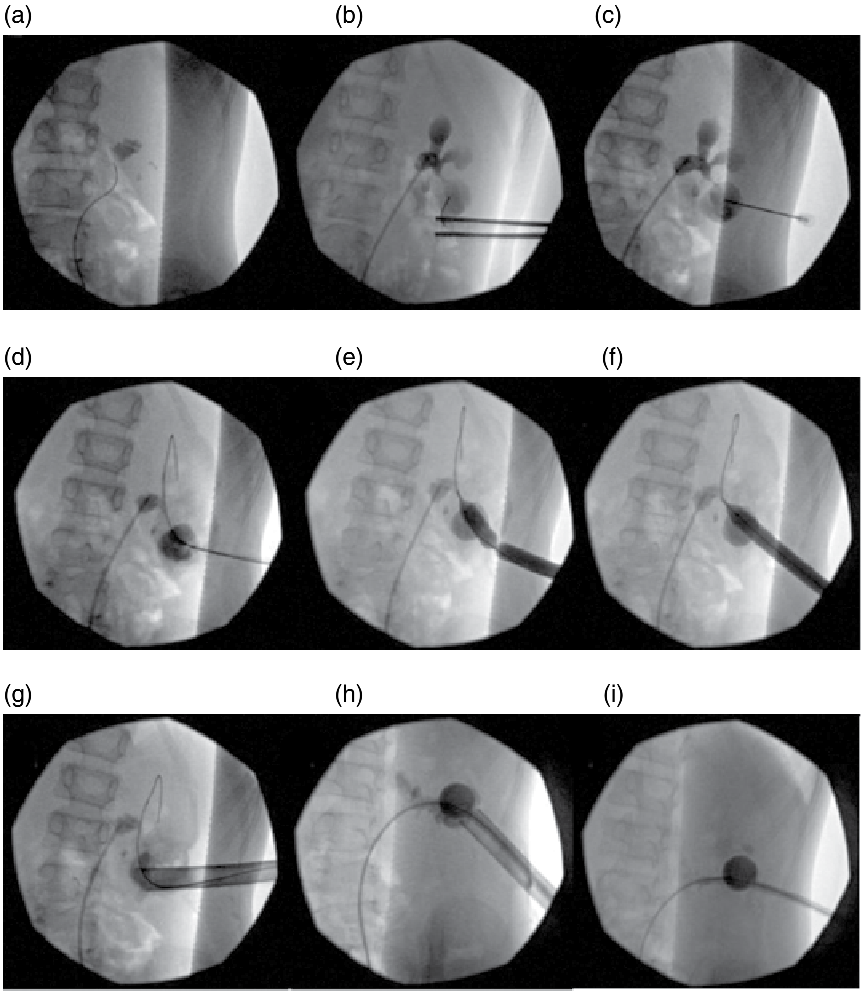

**Figure 27.2** (a) Scout film showing large stone in the renal pelvis with smaller stones in a lower pole calyx, as well as the ureteral catheter after retrograde placement. (b) Lower pole targeted for access after retrograde pyelogram and biplanar fluoroscopy. (c) A 21 gauge spinal needle is inserted with return of clear urine. (d) The guideline is passed through the spinal needle into the collecting system and the tract is serially dilated to 22 Fr. The balloon catheter is then inserted with the distal fluroscopic marker placed into the middle of the lower pole calyx, as shown. (e) The balloon is inflated with waist seen. (f) Continued inflation to 20 atm eliminates the waist. (g) The sheath is placed over the balloon as shown, the guidewire is directed down the ureter into the bladder, and the nephrolithotomy is commenced. (h) A Councill-tip catheter is placed over the wire and balloon inflated to occlude the sheath. Contrast is injected for antegrade nephrostogram demonstrating extravasation and potential injury to the collecting system. (i) A ureteral catheter is placed through the Councill-tip catheter and down the ureter into the bladder while the Councill-tip balloon is placed in the kidney. This is left in place as a nephroureteral stent and secured to the skin. It can be removed later at the bedside after a clamp trial.

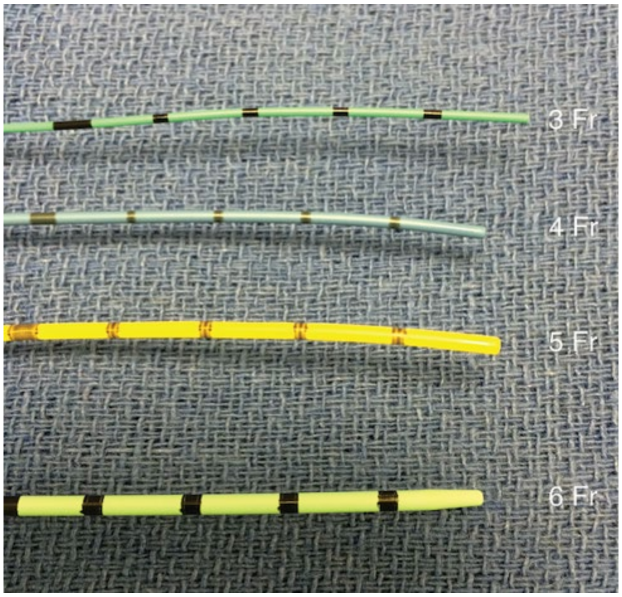

**Figure 27.3** Open-ended ureteral catheters ranging in size from 3 Fr to 6 Fr can be used during pediatric endourology.

Supine PCNL has also been reported, with patients placed in a modified supine position with flexion of the ipsilateral hips and shoulder. Desoky and colleagues were able to achieve stone-free rates of 90.9% with a mean operative time of 65 minutes in 22 children with renal pelvic stones of 2–3 cm [14], while Gamal et al. achieved stone-free rates of 92.5% in 27 children with an operative time of 41 minutes [15]. One patient in each study encountered bleeding that required a blood transfusion.

## Access and tract dilation

A ureteral catheter is placed via the bladder, and is injected with contrast for retrograde pyelography to define the collecting system. Ultrasound guidance can also be used to assist with access to the collecting system, which normally lies in the posterior axillary line. A rotating C-arm is used for biplanar fluoroscopic visualization of the collecting system in the anterior–posterior and oblique positions throughout the procedure. The most optimal tract is determined using the "bullseye" technique (Figure 27.2b). Ideally this would be posterior, and yield direct access, with the shortest distance to the stone, especially when a calyceal diverticulum and/or infundibular stenosis are present. However, for more complex stones or lower pole stones, upper pole access is advantageous as this provides access to both the lower pole calyces, renal pelvis, and ureter [16]. Caution must be taken as this location for access carries increased risk of pneumothorax.

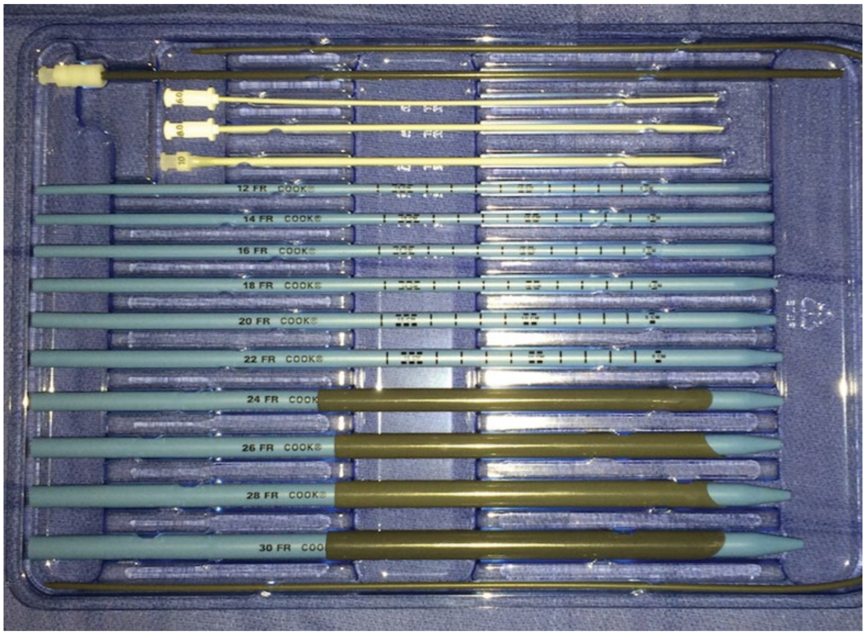
A 21 gauge spinal needle is used to access the desired calyx with return of urine confirming correct placement (Figure 27.2c). A guidewire is passed into the kidney, and through the ureter, and into the bladder. If through and through access is desired, the distal end of the wire in the bladder can be grasped cystoscopically, and brought out through the meatus and placed in a clamp. A small skin incision is made and coaxial dilators (8 then 10 Fr) are placed over the wire into the collecting system, and a super-stiff guidewire is placed and used as the working wire during the procedure. Occasionally, an additional tract may be necessary to perform the procedure, especially if small sheath and nephroscope sizes are utilized, however this is not without additional consequences. Desai et al. found that multiple tracts were associated with lower postoperative hemoglobin decreases and higher transfusion rates [4]. Traditionally, serial dilation has been used with Amplatz dilators (Figure 27.4) over the working wire, followed by a balloon dilator where the distal marker (easily seen on X-ray) is advanced into the calyx (Figure 27.2d). A pressure of about 20 atm should be enough to eliminate the waist seen in the balloon on fluoroscopy (Figures 27.2e,f). The sheath is then advanced over the balloon for simultaneous dilation and tamponade to prevent bleeding and trauma (Figure 27.2 g). Bilen et al. studied different tract sizes (14 Fr, 20 Fr, 24 Fr) utilized during pediatric cases and reported similar efficacy rates in all groups, but there were no transfusions or complications in the 14 Fr group [3]. In our practice, a tract size of up to 30 Fr (same as adult size) can be used with larger teenagers, but in smaller children we dilate to smaller tracts of 20–24 Fr, depending on the size of the child.

## Instrumentation

When PCNL was first used in pediatrics, it was done exclusively using adult-sized instruments and was not performed in children less than 5 years old due to the fear of renal parenchymal damage. It has since been shown that even dilation of the nephrostomy tract up to 30 Fr can be done, and PCNL can be performed consistently and effectively with comparable complication rates, even in very young children less than 5 years of age [3, 5, 17]. Rigid nephroscope sizes used in pediatrics generally range from 10 to 26 Fr (Figure 27.5). Poor visualization and difficulty in the ability to clear larger stone fragments is a downside to using smaller scope sizes. Our preference is to remove the outer 26 Fr sheath of an adult-sized nephroscope (Figure 27.6a) and perform PCNL with just the inner 20 Fr sheath (Figure 27.6b) in children.

After rigid nephroscopy, flexible nephroscopy is usually performed using a 14 Fr flexible cystoscope to inspect

**Figure 27.4** Amplatz straight dilators of sizes 6 Fr to 30 Fr can be used for nephrostomy tract creation. Sheaths in this standard set can be placed over dilators of size 24 Fr or greater.



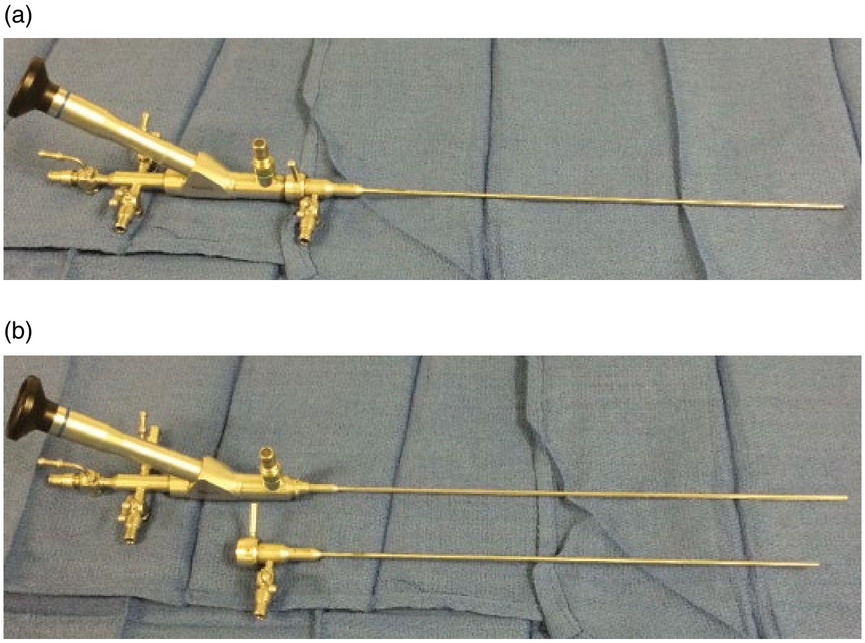


**Figure 27.5** (a) Pediatric nephroscope of size 14 Fr with the outer sheath in place. (b) This can be reduced to 10 Fr after the outer sheath is removed and only the inner sheath is used.

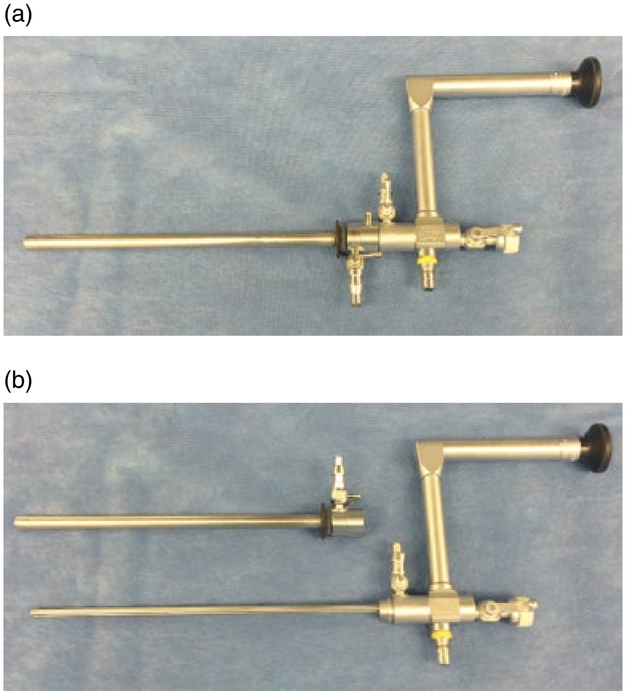

**Figure 27.6** (a) Adult nephroscope of size 26 Fr. (b) The outer sheath can be removed when performing PCNL in children, leaving the inner sheath with a size of 20 Fr. This technique ameliorates the poor visualization and difficult stone removal that occur with pediatric nephroscopes, while still minimizing bleeding from larger tract sizes.

the calyces that may be hard to reach with the rigid scope. Next, ureteroscopy using an 8 Fr flexible ureteroscope may be performed in an antegrade fashion to retrieve any ureteral stones that were pre-existing, or stones that may have dropped into the ureter during PCNL. Mor et al. did not find any evidence of significant scarring nor significant change in differential function on radioisotope scans before and after PCNL in 10 children, and concluded that PCNL performed in children with adult-sized equipment is a safe and efficacious therapeutic option [18]. The larger adult-sized instruments may be more advantageous in children with high-grade hydronephrosis and parenchymal thinning. The larger scopes may help to navigate the larger collecting system, and they may be at less risk of bleeding, as the parenchyma is thinner. Efforts are nevertheless being made in pediatrics to limit unnecessarily large tracts, because they have the theoretic potential for renal damage.

## Mini PCNL

Mini PCNL was first developed by Jackman et al. in 1998, who coined the term “mini-perc” to describe their technique of obtaining access in very young children with large stones. This technique uses an 11–13 Fr peel-away vascular access sheath [19] or a 14 Fr sheath with removable obturator (Figure 27.7) passed over the working wire and through the calyx under fluoroscopic guidance. This system allows instruments to work through the access sheath with enough clearance to allow low-pressure irrigation. The smaller tract sizes afforded with mini PCNL can theoretically improve maneuverability of instruments and decrease blood loss during the case, at the expense of impaired visualization if bleeding does occur. Thus, this technique has been discouraged with larger stone burdens. Large series have shown stone-free rates of 76–91.4% with operative times of 76–109 minutes and

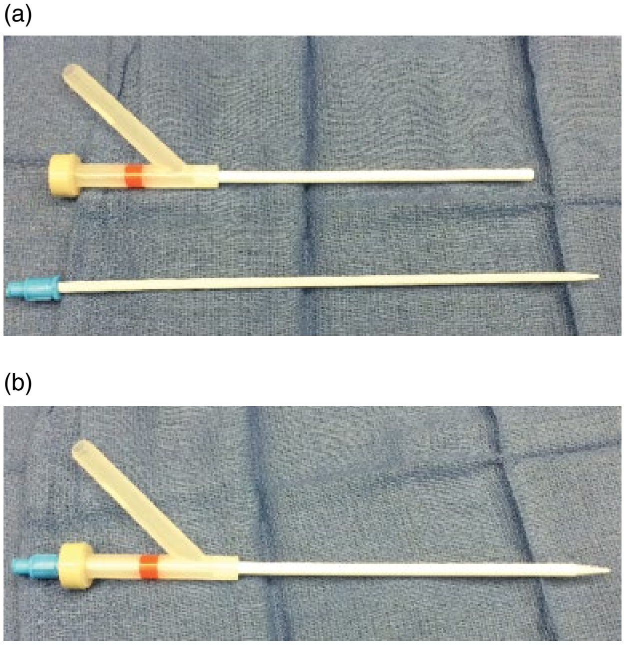

**Figure 27.7** Mini PCNL kit. (a) The set contains a removable obturator and a 14 Fr sheath which can accommodate smaller sized nephroscopes. (b) The obturator is placed through the sheath and subsequently over the guidewire for placement within the nephrostomy tract.

complication rates ranging from 10.6 to 36.3%, with very low rates of high-grade complications according to Clavien classification [20].

Studies comparing standard and mini PCNL in children have shown mini PCNL to have similar stone-free rates with lower hospital length of stay, postoperative pain scores and analgesic requirements, and complication rates, however with longer operative times. Compared to retrograde intrarenal endoscopic surgery, mini PCNL appears to have better stone-free rates, lower operative times, comparable complication rates, but longer hospital stays [21]. Kamal et al. have advocated for the development of equipment that creates even smaller tract sizes for performing PCNL, with sheath diameters reaching as low as <5 Fr ("micro PCNL") [20, 21]. One investigation retrospectively compared PCNL in children using adult (24 Fr), pediatric (18 Fr), and mini (9.5 Fr) nephroscopy, and found stone-free rates of 71.4%, 75.8%, and 78%. The mean hematocrit drop was less in the mini group (0.8) compared to the pediatric (1.7) and adult (1.9) groups as well. Access, total operative time, length of stay, and complication rates did not differ significantly [22].

## Energy sources

Various energy sources can be used for stone fragmentation and retrieval during nephrolithotomy, and there is not much of a difference when performing PCNL in children. Electrohydraulic lithotripsy (EHL) has been studied with 89.8% stone-free rates and a 14% transfusion rate [4]. Salah and associates achieved 98.5% stone-free rates using ultrasonography for fragmentation with only a 0.7% transfusion rate but an 8% rate of urine leak [23]. Holmium laser lithotripsy can be utilized as well, and Bujons et al. reported PCNL to treat staghorn and complex stones using a high-powered holmium:YAG laser in 35 pediatric patients through an 18 Fr tract. Mean stone burden was 4.46 cm, mean operative time was 150 minutes, and in three cases multiple tracts were used. The stone-free rate was 78% after one procedure, and there were two Clavien II complications with no transfusions [24]. Along with fragmentation, stone graspers, baskets, and suction may all be used for stone retrieval. Any residual stones >2 mm should be removed as they can be a nidus for further stone growth and formation.

## Postoperative drainage

At the end of the procedure, an antegrade nephrostogram is performed to identify any residual stones along with assessing for any injuries to the collecting system (Figure 27.2 h). The decision to place a ureteral stent versus a nephrostomy tube are at the discretion of the surgeon and patient. If second-look nephroscopy or a second PCNL is planned, a nephrostomy tube is preferred to allow for direct access to the renal collecting system. A pigtail catheter is useful in children as they are easy to conceal and thus difficult for younger patients to pull on. A clamp trial is performed after two days with subsequent removal if the patient tolerates the clamping without flank pain, nausea, vomiting, fevers, or chills. If an additional percutaneous procedure is not anticipated, a ureteral stent can be placed in an antegrade fashion with cystoscopic removal at a later date in the operating room under moderate sedation (in contrast to adults, in which the stent can simply be removed in the office using flexible cystoscopy with a local anesthetic). Although the data for tubeless PCNL in pediatrics are sparse, one group reported lower pain scores, no intravenous narcotic usage, and shorter hospital stays in 20 children who had undergone tubeless PCNL compared to a matched cohort of children who had PCNL using a tube or stent. One patient with tubeless PCNL had a urine leak [25].

We recommend stenting both the nephrostomy tract and the ureter. A prepackaged nephroureteral stent specifically made for this purpose can be placed. We have found a nephroureteral catheter can be made on the operating table by placing an open-ended ureteral stent through a Councill or Malecot catheter and passing this down the ureter into the bladder while the larger outer catheter's tip is left in the renal pelvis, as both catheters exit from the nephrostomy tract together (Figure 27.2i).

## Staged procedures

In patients with a large stone burden, a staged PCNL may be needed to achieve stone-free status. Typically, the second-look PCNL is done 2–3 days after the initial PCNL during the same hospitalization and through the prior tract. Of note, we do not recommend bilateral procedures to be performed in a single sitting in children. If bilateral stones exist, separate procedures should be done on each kidney at different times to allow for renal recovery after one kidney is addressed surgically. Flexible endoscopy is a useful tool when a second stage is needed, and can be done without using any fluoroscopy. The goal of each procedure should be for the complete removal of all stone fragments. However, in some patients with very large stone burdens, this is sometimes unavoidable [26].

### Sandwich therapy

When additional procedures are needed, the surgeon may elect to utilize "sandwich therapy." This is where ESWL is used following an initial percutaneous procedure to treat any inaccessible stone fragments. Then, if necessary, a second-look PCNL through the prior tract (to remove any residual fragments) can then be performed after the ESWL (which has been "sandwiched" between the two PCNL procedures). This method can be performed during the same or different hospital stays. Mahmud and Zaidi found their stone-free rates after PCNL increase from 60% to 100% after adjuvant ESWL (PCNL + ESWL) was performed. Mean age was 3.8 years and mean stone burden was 2.4 cm [27]. Another large study of 169 children with a mean stone size of 3.1 cm showed stone-free rates increase from 59% to 93.8% after "sandwich therapy" (PCNL + ESWL + PCNL), with a 3.6% transfusion rate [28].

## Complications

Fever in the immediate postoperative period occurs at a rate of 31% and is the most frequent complication after pediatric PCNL, but most often this is transient and non-microbial as the postoperative infection rate is only 6% [3, 20]. However, the high irrigation pressures within the kidney during PCNL along with bacteria that are harbored within the calculi that are released during stone fragmentation place the patient at risk of urosepsis postoperatively. Because of this, all patients are screened preoperatively with a urine culture, and placed on culture-specific antibiotics. An intravenous first-generation cephalosporin such as cefazolin is used during the procedure. Patient should also be covered with antibiotics for the first few days after surgery, and many providers elect to keep patients on prophylaxis until all tubes and stents are removed. There is no consensus on whether or not continuous, daily, low-dose antibiotic prophylaxis is warranted in patients with indwelling or external urinary catheters, but the AUA does recommend a dose of antibiotic be given just prior to stent manipulation or catheter/tube removal to prevent bacterial release from these indwelling structures, which are usually colonized [29]. One prospective randomized study in 95 patients after ureteral stent placement showed no significant differences in rates of symptomatic (10% vs. 9%) and febrile (6% vs. 7%) urinary tract infections for patients, whether or not daily prophylactic antibiotics were used [30]. During surgery, a piece of the stone should be sent for culture, and antibiotic coverage tailored to sensitivities.

If there is an injury to the collecting system and subsequent urine leak (which can be seen as extravasation of contrast on antegrade nephrostogram), prolonged stenting or tube drainage should be employed initially for six weeks. Placement of a perinephric drain may be necessary if a large urinoma develops, and does not resolve with drainage of the collecting system. Injury to the pleural space may occur during attempted access to an upper pole calyx. When suspected, a chest X-ray should be obtained and a chest tube may be required if there is a large pneumothorax, hemothorax, or urothorax.

A drop in hemoglobin requiring transfusion is not uncommon after pediatric PCNL and occurs at rates of 0.4–24%; it occurs more commonly when tract size exceeds 22 Fr [4, 20]. Furosemide is given between units if multiple transfusions are needed. If excessive bleeding is seen in the kidney and nephrostomy tract during the case, a balloon tamponading catheter should be placed through the tract and left in place until bleeding resolves, with a trial of balloon decompression before the tamponade catheter is removed. If the patient requires multiple transfusions, or if the patient presents with delayed bleeding weeks after PCNL, they should be sent for angiographic evaluation for a pseudoaneurysm or arteriovenous fistula. If the source of bleeding is found, superselective vascular embolization can potentially be performed, which is successful in controlling 80% of post-PCNL bleeds [31].

Injuries to adjacent organs vary depending on which organ is harmed and the severity of the damage. If a colonic perforation is diagnosed postoperatively, it is likely retroperitoneal and minimally invasive management can be attempted initially: the nephrostomy tube is withdrawn from the kidney into the colon as a colostomy tube, and an indwelling ureteral stent is inserted.

The patient is placed on bowel rest with total parenteral nutrition. Broad-spectrum intravenous antibiotics including coverage of enteric anaerobic organisms (e.g. with metronidazole) should be employed as well. This may avoid the need for exploratory laparotomy, but general surgical consultation should also be obtained [32].

## Conclusions

PCNL has been shown to be an effective therapeutic option for children with renal calculus disease compared to other modalities. In a large review of over 600 children treated for urolithiasis, PCNL and mini PCNL were found to have superior stone-free rates of 85% and 100%, respectively, compared to ESWL at 68% and ureteroscopy at 66%. Open surgical removal of kidney stones had a higher stone-free rate (94%) than the PCNL group, but the open group also had a threefold higher transfusion rate when compared to PCNL [33]. With further technologic advances, and smaller instruments under development, PCNL will continue to advance as a treatment alternative for children with large stones. Therefore, PCNL can be considered a safe and effective treatment option for large kidney stone burdens in children, even those of a very young age.

## Introduction

Percutaneous nephrolithotomy (PCNL) is usually performed for large stones, abnormal renal anatomy, and stones not amenable to ureteroscopy (URS) or shockwave lithotripsy (SWL). Advantages of PCNL include superior stone clearance, limited convalescence, and cost-effectiveness [1]. Although major complications are possible, studies have demonstrated overall safety and effectiveness of this technique for complex calculi [2]. Over time, the limits of percutaneous surgery have expanded. In this chapter we review the role of percutaneous surgery in the treatment of three benign conditions: calyceal diverticula, infundibular stenosis with hydrocalyx, and symptomatic renal cysts.

## Calyceal diverticula

A calyceal diverticulum is a congenital, smooth-walled, nonsecretory urothelium-lined cavity that communicates with the main collecting system via a narrow channel. Urine is received by the diverticulum through passive retrograde filling [3, 4]. Calyceal diverticula were first described in 1841 by Rayer [5] and named diverticula by Prather in 1941 [6]. Diverticula occur when small ureteral buds fail to degenerate in 0.21–0.6% of patients, with 3% presenting bilaterally [7–11]. The majority are found in the upper pole (49%) and middle pole (30%) with an average size of 17 mm [3]. Stones occur in 9.5–50% of diverticula [7, 8]. Occasionally, calyceal diverticula can be associated with pain, hematuria, and recurrent urinary tract infections (UTIs) [8, 9]. Complete obstruction of the diverticular neck can lead to sepsis, abscess formation, or hypertension [12].

The cause of diverticular stone formation is controversial. Particle retention due to obstruction and stasis has been proposed, as have underlying metabolic abnormalities in 50–100% of patients [13–18]. Matlaga et al. compared the 24-hour urine studies of calyceal diverticulum patients with calcium oxalate stone formers and normal patients [15]. Although the urinary stone risk parameters of calyceal diverticulum patients were similar to those of the calcium oxalate stone-forming group, urine aspirated directly from the diverticulum of three patients demonstrated significantly lower supersaturation of calcium oxalate compared to urine obtained from the renal pelvis of the same patient, implicating stasis as a contributor to calculi formation.

### Diagnosis

The majority of patients are asymptomatic, with incidental diagnosis on imaging performed for other indications. The differential diagnosis includes renal or parapelvic cysts, hydrocalycosis (hydronephrosis of a calyx) secondary to infundibular stenosis, cystic tumors, and solitary abscess. In appropriate clinical settings, cortical cavitation secondary to renal tuberculosis has similar appearance [12]. In children, calyceal diverticula commonly present with UTIs and association between calyceal diverticulum and vesicoureteral reflux should be ruled out [19, 20].

The workup includes urinalysis, complete blood count, basic metabolic panel, and imaging of the abdomen. A renal ultrasound or noncontrast computed tomography (CT) scan is typically performed. Renal ultrasound will accurately diagnose calyceal diverticulum in 80% of cases [21] (Figure 28.1). The diverticulum without stones will have appearance and echotexture similar to renal cysts. When echogenic material is present, the patient is scanned in different positions to demonstrate gravitational changes of the content, a tell-tale sign of calyceal diverticulum [3]. The classic ultrasound finding of "milk

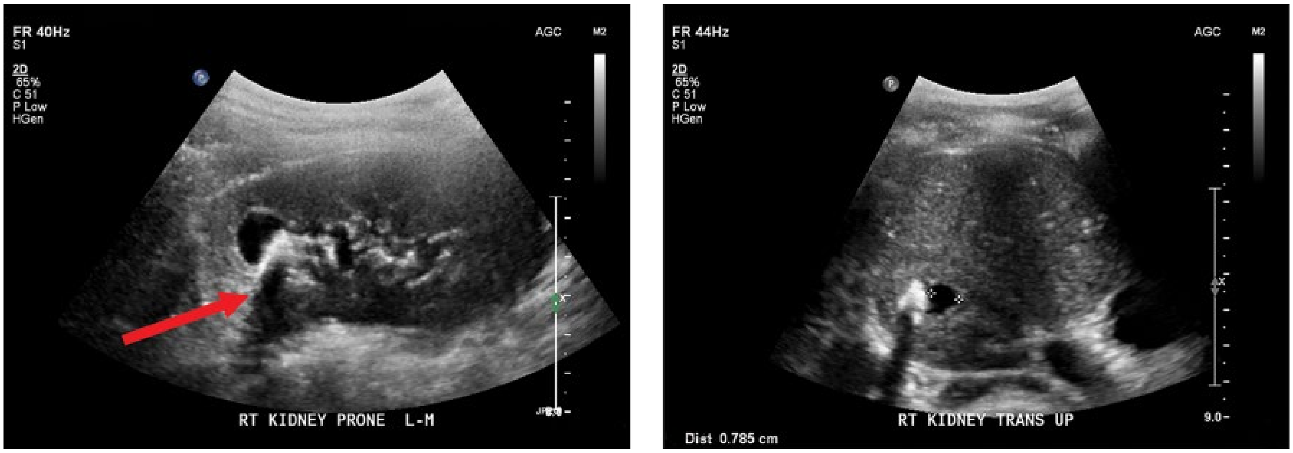

**Figure 28.1** Coronal and axial appearances of calyceal diverticulum on ultrasound. Arrow denotes posterior acoustic shadowing indicating presence of diverticular stone.

of calcium" is a colloidal suspension of precipitated calcium crystals [22]. The milk of calcium will appear as a meniscus-like, semilunar calcification that changes position on upright and lateral decubitus radiographs [23]. Calyceal diverticula are seen on noncontrast CT as a small, round, low-attenuation area adjacent to the calyx or as a dilated outpouching from the collecting system containing a stone [24] (Figure 28.2).

Prior to any treatment, the location of the diverticulum and communication with the rest of the collecting system should be confirmed with a CT urogram or an intravenous pyelogram (IVP). Most calyceal diverticula will opacify if they have a significant communication with the collecting system [8]. Since the diverticulum itself is nonsecretory, the opacification will occur later in the examination as it is filled in a retrograde fashion from the collecting system, necessitating delayed images [3, 25] (Figure 28.3). A retrograde pyelogram can be helpful in locating the neck of the diverticulum. Where the calyceal infundibulum is obstructed, the diverticulum will not opacify with contrast administration and becomes difficult to differentiate from a complex renal cyst. This finding is important for surgical access planning. Notably, the failure to demonstrate the diverticular neck does not detract from the diagnosis [11].

## Treatment

Patients with asymptomatic calyceal diverticula do not require treatment. Pain, recurrent UTI, hematuria, symptomatic calculi, or progressive renal damage are indications for intervention [7]. Traditionally, open marsupialization and fulguration of the diverticular cavity or partial nephrectomy were performed. Nowadays minimally invasive options for symptomatic calyceal diverticula include SWL, URS, PCNL, and laparoscopy. Treatment options depend on diverticulum location, stone burden, and size [26].

SWL for the treatment of calyceal diverticula is controversial. Although at short-term follow-up SWL provided symptomatic improvement in 36–70% of patients, stone-free rates were low at 4–20% [27, 28]. The highest reported stone-free rate remains suboptimal at 58% [29]. With longer observation, patients initially rendered symptom-free with SWL will become symptomatic and require retreatment [27]. Thus, SWL is rarely considered as monotherapy for calyceal diverticula. To prevent stone recurrence, eradication of the diverticulum should accompany stone removal, a goal that is

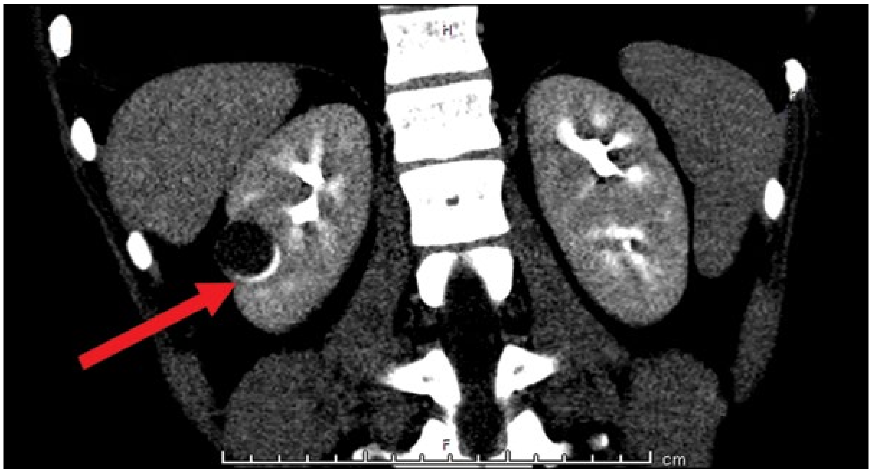

**Figure 28.3** Calyceal diverticulum with classic appearance of semilunar "milk of calcium" deposits on delayed images of CT abdomen.

rarely achieved with SWL [30, 31]. Furthermore, while SWL may be effective in stone fragmentation, the passage of these fragments remains a concern. The narrow diverticular neck that is hypothesized to cause stone formation through stasis in the first place can prevent fragment clearance [3].

Ureteroscopy is more effective at stone clearance than SWL. It is minimally invasive and can allow ablation of the diverticular cavity at the same time. Retrograde URS is a reasonable option for selected patients with a diverticulum in the upper or middle portions of the kidney when the stone burden is small and the diverticular neck is short and easily accessible [3, 30, 32]. Lower pole calyceal diverticula are often at an acute angle that precludes retrograde management. Identification of the diverticular neck can be difficult with a retrograde approach and may account for the lengthy operative times (1.25–4 hours) reported in some URS series [32, 33]. In one series the ostium could not be identified at all in a third of patients [12]. Injection of contrast or methylene blue (with subsequent washout from renal pelvis followed by the slow drainage of the dye from the diverticular ostium) can be useful in identifying the ostium [34]. The diverticular neck is then incised or dilated, allowing stone clearance and cavity ablation with either a holmium:YAG laser or a Bugbee electrode. Stone-free rates for URS range from 19% to 90%, but diverticular obliteration is as low as 18%; furthermore, a significant number of patients demonstrate residual symptoms and require retreatment [31, 33, 35–38]. Bas et al. compared 29 PCNL with 25 URS cases, with similar stone-free rates but higher major complication rates in the PNL group; however the stones in the PNL group were larger [39]. Auge et al. compared 22 cases of PCNL with 17 URS cases and concluded that PCNL was universally better than URS for all stone locations and should be used as a primary modality for calyceal diverticular stones [36].

Laparoscopy is suitable for large anterior diverticula with a thin layer of overlying parenchyma and significant stone burden [40, 41]. Diverticula in ectopic kidneys, where a percutaneous approach will be hampered, are another indication. However, the laparoscopic approach is more invasive than PCNL with lengthy operative times (up to 2.5 hours) even in experienced hands, and should only be considered in select cases [41–43].

Percutaneous treatment of calyceal diverticulum calculi achieves high stone-free rates (87.5–100%) and allows simultaneous obliteration of the diverticular cavity in 76–100% [25, 27, 31, 44–49]. Over 90% of patients report symptomatic relief with percutaneous treatment [27, 36, 44–46, 50], with durable 100% success rates at 38 months follow-up in another study [46]. In a report from Kim et al., operative times were <60 minutes and 20 of 21 patients were sent home tubeless on postoperative day 1 [48]. Typically, percutaneous access is performed directly into the calyceal diverticulum to allow use of a rigid nephroscope as successful treatment of stone-containing diverticulum is contingent on complete stone removal [48]. Direct puncture of a small or upper pole diverticulum can be difficult, requiring puncture of a neighboring calyx. The diverticulum is then entered indirectly by perforating the wall of the diverticulum or by entering in a retrograde fashion through the diverticular neck [51]. However, this "indirect assess" technique has a lower rate of diverticular cavity obliteration (50% vs. 79%) [45, 52]. Finally, percutaneous balloon dilatation of calyceal diverticular infundibula in the absence of stones has also been described [53].

Controversy exists regarding optimal management of the diverticulum following complete stone removal. An existing communication to the collecting system can be dilated and stented or created anew (neoinfundibulotomy), in an effort to promote drainage [27, 38, 45, 47, 50]. Both techniques carry risk of bleeding and require the placement of a nephrostomy tube for a prolonged period to ensure patency. Another treatment strategy is to fulgurate the diverticulum. This can be achieved percutaneously, without ureteral catheterization or infundibular cannulation, with 87.5–100% diverticular ablation rates [46, 48]. Although calyceal diverticulum is lined by a nonsecretory endothelium, most authors advocate fulguration at the time of PCNL [30, 33]. Dilation or incision of the diverticular neck without fulguration results in complete ablation of the diverticulum in only 30% of cases [54], in contrast to the 76–100% ablation rate when fulguration is performed [27, 45, 46, 55]. Others suggest that diverticular wall trauma from the percutaneous dilation process itself is sufficient to ablate the diverticular lumen [44]. If fulguration is to be performed, avoiding infundibular dilation will maximize the chance of diverticular obliteration. Krambeck and Lingeman compared dilation of the infundibular tract with cavity fulguration alone. The “fulguration only” technique had a higher initial stone-free rate (94.2% vs. 77.3%) with shorter length of stay. The diverticulum either disappeared or reduced in size in 89% of patients who had follow-up IVP at three months [56].

## Technique

The procedure is preceded by careful review of imaging to assess the degree of diverticular filling. The percutaneous approach is typically achieved with biplanar fluoroscopy and is thus reliant on visualization of the radiopaque target [57]. If the diverticulum does not fill retrogradely with contrast and/or if the stone is radiolucent, the following steps can be taken. First, contrast can be instilled into the diverticular cavity via a retrograde ureteral catheter (Figure 28.4). Care must be taken to avoid overfill and contrast extravasation, as this makes subsequent fluoroscopic targeting difficult. Second, if the diverticulum does not readily fill with contrast due to stenosed infundibulum, a CT- or ultrasound-guided pre-PCNL opacification of the diverticulum by interventional radiology is an option [25]. A 20G spinal needle is manipulated under radiographic guidance into the diverticulum. Iodinated contrast is gently instilled until resistance is encountered and kidney–ureter–bladder (KUB) imaging is performed to confirm opacification of the target (Figure 28.5). The patient is then transported promptly to the operating room as too long a delay may permit absorption of the contrast and loss of the target. Lastly, ultrasound guidance can be utilized [58]. Unfortunately, it is difficult to monitor guidewire manipulation with ultrasound imaging.

If the target diverticulum is radiopaque, a single-stage procedure is performed where percutaneous access is directed straight onto the stone [48] (Figure 28.6). The patient is anesthetized and positioned prone without an external ureteral catheter. A C-arm is used to visualize the diverticular calculi. When possible, a direct infracostal puncture (to reduce risk of pleural injury) is performed using an 18G diamond-tipped needle and a biplanar fluoroscopic triangulation technique [59]. A 0.035-inch J-tipped movable core guidewire is coiled inside the diverticular cavity, taking care to avoid wall perforation with the stiffer portion of the wire. The flexible distal end of the movable core J-wire can be adapted to the size of the diverticulum, while the wire proximal to the moved core remains stiff enough to function as the

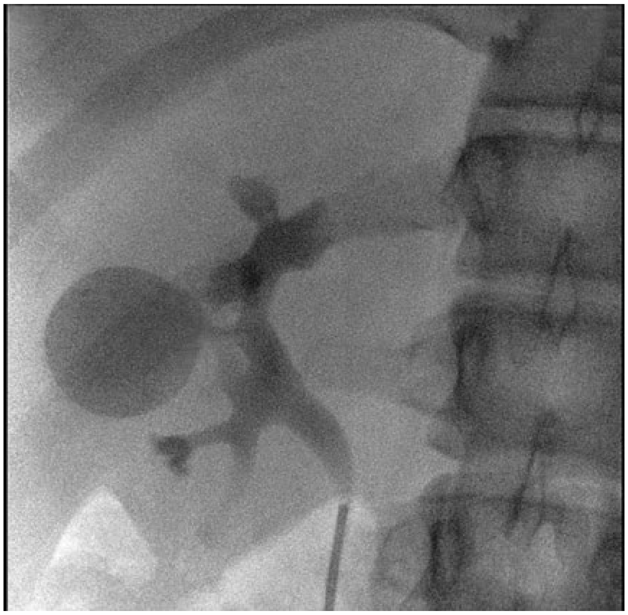

**Figure 28.4** Retrograde pyelogram of a calyceal diverticulum. Contrast instillation allows fluoroscopic targeting for percutaneous access.

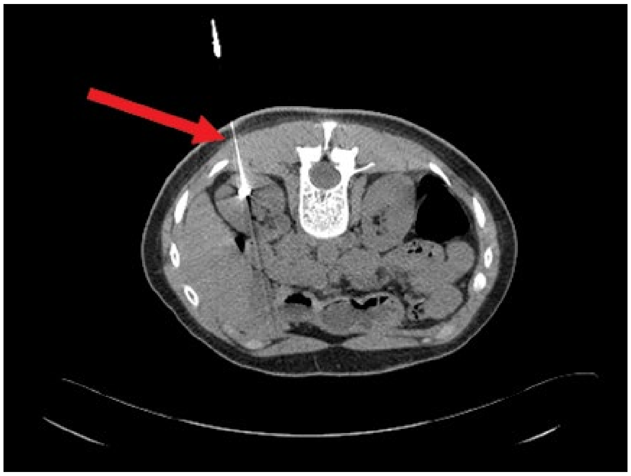

**Figure 28.5** CT-guided contrast instillation to allow fluoroscopic targeting of radiolucent obstructed calyceal diverticulum.

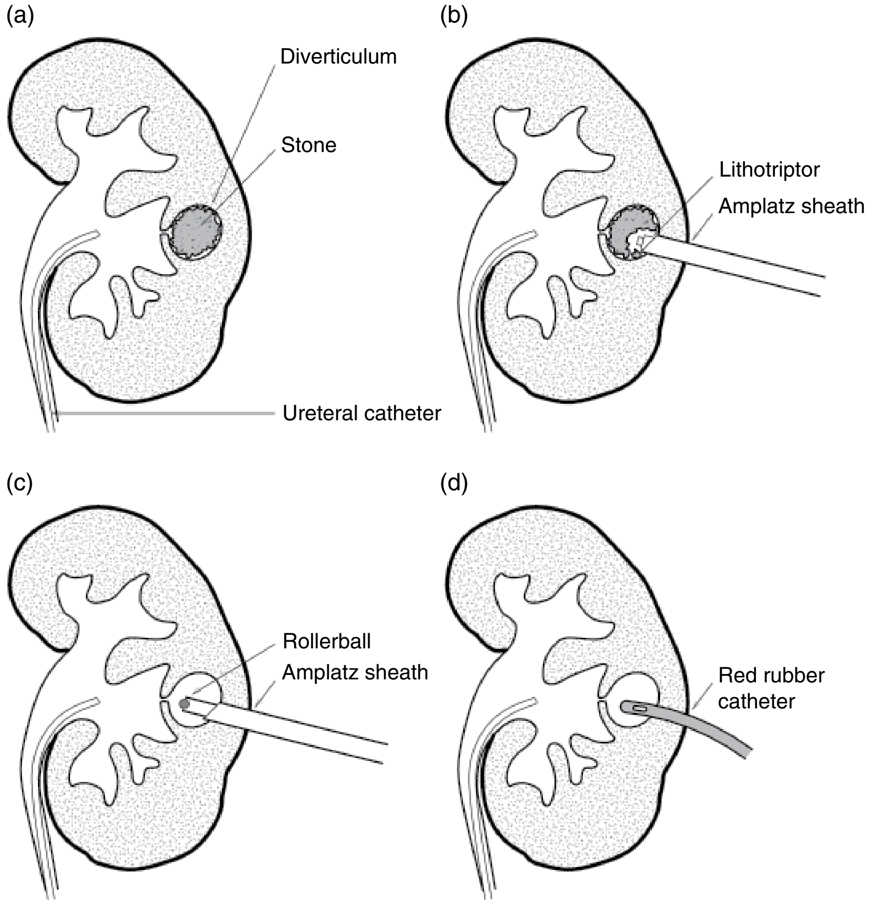

**Figure 28.6** Single-stage percutaneous approach to calyceal diverticulum with stones. (a) Stone in a midpole diverticulum. working wire. With the J-wire in place, an 8/10 Fr coaxial dilator is passed over the J-wire in a sequential fashion. The 8 Fr dilator is removed and a second 0.035-inch J-tipped movable core wire is coiled inside the diverticulum and used as the safety wire. The tract is balloon dilated over the working wire, carefully placing the balloon dilator and the wires to avoid perforation of the back wall. A 30 Fr Amplatz sheath is then passed over the balloon dilator under fluoroscopic guidance. The taper on the distal end of the balloon dilator will preclude placement of the sheath directly into the diverticular space unless the diverticulum is large. Next, an offset 24 Fr rigid nephroscope is placed inside the access sheath using normal saline irrigation. Alligator forceps (11 Fr) are used to manually dilate the part of the tract immediately adjacent to the diverticulum, allowing for advancement of the scope and subsequently the sheath into the diverticular lumen. Once inside the diverticulum, ultrasonic lithotripsy or grasping forceps are used to remove the stone burden. Stone culture is obtained by using grasping forceps to transfer a stone fragment directly into the culture cup, where it is ground with a sterile hemostat. After removal of all stone material the entire cavity should be inspected for presence of a flattened renal papilla, indicating an obstructed hydrocalyx rather than a calyceal diverticulum (see Video 28.1).

The irrigant is switched to 1.5% glycine (or sorbitol 2.7% with mannitol 0.54%) to fulgurate the diverticular lining with a resectoscope and a rollerball electrode. Low-energy electrocautery (20 W coagulation, 0 W cut) settings are used. The tip of the rollerball electrode can be bent to aid fulguration of difficult-to-reach areas in the diverticulum or a Bugbee electrode can be used. Fulguration with holmium:YAG laser has also been described [60]. The infundibular communication is neither assessed nor dilated. An 18 Fr red rubber catheter or, in larger cavities, a 10 Fr Cope loop catheter is placed in the cavity. Proper placement of the drainage tube is confirmed by contrast instillation under fluoroscopy. If the diverticulum is small, the red rubber catheter acts as a perinephric drain, as it usually becomes dislodged from the diverticular cavity. The drainage tube can be removed on postoperative day 1 if drainage is minimal. Occasionally, if the communication with the renal collecting system is large, considerable (i.e. >100 ml) drainage from the nephrostomy tube may occur. In this situation the nephrostomy tube is left for one week to allow the tract to mature.

### Potential complications

Complications associated with percutaneous access in general also apply to percutaneous treatment of calyceal diverticula: hemorrhage, retroperitoneal extravasation, pneumothorax, hemothorax, and adjacent organ injury (see Chapters 32–35). Percutaneous access to anterior diverticula has increased bleeding risk due to longer tract distance through renal parenchyma [61]. If infundibular stenosis is misdiagnosed as a calyceal diverticulum and fulguration of a dilated calyx with functioning papillae is performed without infundibular dilation, urinoma with fistula formation can occur. Since only the diverticulum area is treated, we make every effort to place our access site infracostal, thus substantially decreasing the risk of pleural injury and hydrothorax. Use of monopolar electrocautery carries theoretical risk of dilutional hyponatremia, although typically only a short time is spent ablating the diverticular cavity.

Guidewire control is essential, especially with small diverticula. As we do not typically pass guidewires into the main renal collecting system, utmost attention must be paid to keeping the guidewires secure when passing dilators and balloons to avoid loss of access. If serial dilation is performed, a false passage can be created through repetitive insertion and removal of dilators over a poorly secured access wire. If balloon dilation is performed, avoiding advancing the dilator and access sheath too far into the diverticulum will reduce risk of posterior wall perforation and hemorrhage. For small diverticula, we suggest only placing the tip of the balloon dilator into the diverticulum with the access sheath just outside the diverticulum. The remainder of the tract is then manually dilated under direct vision using grasping forceps.

### Posttreatment evaluation

Retrieved stone material is sent for stone analysis. Stone culture specimen is sent as preoperative urine cultures in patients undergoing PCNL have been shown to be unreliable [62]. This stone culture is particularly useful in guiding antibiotic therapy in the rare event of post-PCNL sepsis. Stone-free status is assessed after the procedure with a noncontrast CT scan on postoperative day 1 prior to removal of the drainage tube. Imaging of the collecting system is performed at three months either with CT urogram or an IVP to assess resolution of the calyceal diverticulum. Current literature supports metabolic evaluation for patients with calyceal diverticula calculi as discussed previously.

## Infundibular stenosis

Infundibular stenosis is defined by a dilated calyx draining through a narrowed infundibulum into a nondistended renal pelvis (Figure 28.7). It can be congenital, caused by extrinsic compression (malignancy, retroperitoneal fibrosis) or intrinsic narrowing (infection, stones, iatrogenic injury, or renal surgery) [63–65]. Genitourinary tuberculosis (TB) is the most common cause of infection-induced infundibular stenosis and should be considered in appropriate clinical setting. In children, infundibular stenosis is on the spectrum of pyelocalyceal dysgenesis and can be associated with contralateral multicystic dysplastic kidney in up to 2.5% of patients [66]. Fraley's syndrome, a rare cause, is due to a crossing segmental artery, typically affecting an upper pole calyx [67]. The mechanism is similar to ureteropelvic junction (UPJ) obstruction due to a lower

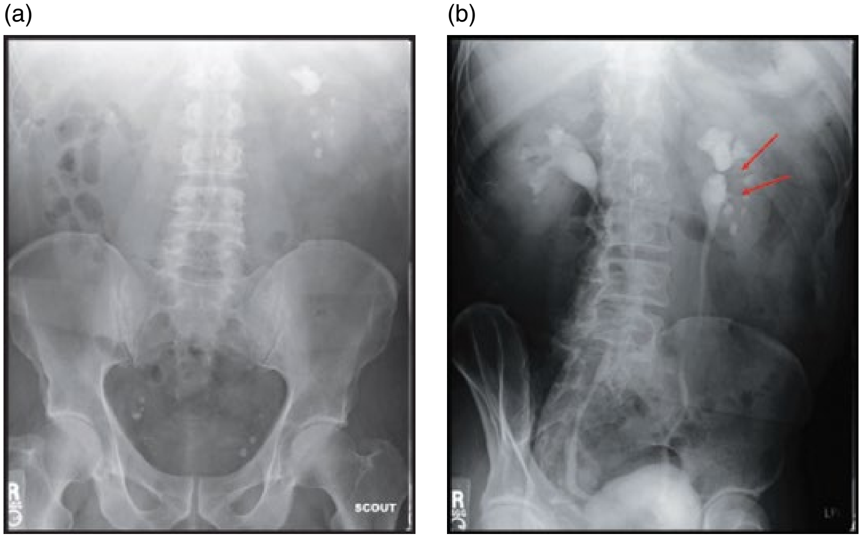

**Figure 28.7** (a) Plain abdominal X-ray of the abdomen and pelvis demonstrating multiple calyceal stones in the left kidney. (b) Excretory urogram demonstrates stenosis of multiple infundibuli leading to the stone-containing calyces (arrows).

pole crossing vessel. Unlike a calyceal diverticulum, urine production continues, resulting in a hydrocalyx. Since infundibular stenosis is so rarely encountered, the true incidence of the disorder is unknown. Occasionally, the stenosis will be so severe that the infundibulum becomes completely occluded; this is termed an excluded calyx.

### Diagnosis

Typically, infundibular stenosis is asymptomatic and discovered incidentally. Acquired infundibular stenosis, even if asymptomatic, can lead to progressive renal failure, with some authors advocating surgical correction [68]. Pain is the most common presenting symptom, followed by hematuria and recurrent UTIs. Stone material may be present in the hydrocalyx [63]. The differential diagnosis includes calyceal diverticulum and renal cyst. While initially suspected on imaging when dilated cystic outpouching of collecting system is seen, true diagnosis requires endoscopic visualization of a papilla in the dilated hydrocalyx. An arteriogram or CT angiogram is useful if a crossing renal artery is suspected, especially for surgical planning [69, 70].

### Treatment

The two indications to treat infundibular stenosis are to relieve obstruction of the dilated calyx and to permit access to a stone or tumor within the calyx. Any reversible causes (e.g. a crossing vessel) should be investigated. Laparoscopic, ureteroscopic, and percutaneous approaches exist.

In general, hydrocalyx with functioning draining parenchyma should not be approached laparoscopically due to risk of urinoma [42]. The ideal candidate is a poorly functioning anterior calyx. The renal parenchyma should be thoroughly fulgurated to destroy any residual functional tissue.

Ureteroscopy is possible if the infundibulum can be seen and cannulated with a wire [69, 70]. It is opened using the holmium laser or balloon dilated, then stented for 4–6 weeks to allow adequate healing. Unfortunately, long-term follow-up studies are lacking. Kieran et al. reviewed experience of 12 URS cases for hydrocalyx, with technical success in most but symptom relief in only half and recurrence in a third. Fortunately, the URS trial did not preclude subsequent percutaneous procedure [71]. As with calyceal diverticula, retrograde flexible ureteroscopic approach is difficult for lower pole obstructed calyces. Percutaneous treatment is possible with direct puncture into the hydrocalyx or by indirect puncture into an adjacent calyx, depending on the anatomy of the affected calyx.

### Technique

Percutaneous access to the calyx is obtained as described above. Retrograde instillation of contrast usually outlines the calyx in question. If the calyx is completely excluded and no stone material is present for fluoroscopic targeting, an ultrasound or CT-guided access is necessary. A needle and then a guidewire are advanced through the calyx towards the collecting system. If the guidewire does not easily traverse the infundibulum, it is coiled in the hydrocalyx, similar to a calyceal diverticulum. After balloon dilation of the percutaneous tract, the access sheath is positioned and the calyx is inspected with a rigid or flexible nephroscope to identify the papilla and the infundibulum. It is important to remove all stones from the calyx prior to infundibular dilation to prevent stone migration into the renal parenchyma. If the infundibulum is not easily identified, retrograde instillation of methylene blue via the external ureteral catheter is useful. In the case of an excluded calyx, a simultaneous URS may be used while the surgeon observes the calyx through the nephroscope. Movement produced by the ureteroscope allows for identification of the main collecting system and may permit successful cut down through the stenosed segment to the wire.

Once a hydrophilic wire is advanced across the infundibulum, it can then either be dilated with a 6 mm × 4 cm balloon or incised with a holmium:YAG laser or a cold knife. Incision is performed away from any obvious pulsations, ideally at the superior and inferior aspects. Multiple superficial cuts are preferred to a single deep cut to limit blood loss [72, 73]. Incision can then be augmented with fluoroscopically guided balloon dilation. Balloon dilation of longer stenotic infundibula reduces the risk of bleeding and extravasation associated with holmium:YAG incision [37].

After dilation of the infundibulum, the hydrocalyx is drained by placing a ureteral stent with the proximal coil in the hydrocalyx and distal coil in the bladder. One or two double-J stents can be used since stent size does not affect subsequent patency of the infundibulum [63, 72]. We prefer an endopyelotomy stent with a larger 14 Fr proximal diameter tapering to 7 Fr distally. Another drainage option is a nephrostomy tube across the infundibulum with coil in the renal pelvis. No study has demonstrated that eventual infundibular patency is affected by type, size, or duration of drainage [63].

In an indirect approach to the infundibulum, access is gained into a calyx adjacent to the hydrocalyx. The flexible nephroscope is then used to identify the stenosed infundibulum that is then balloon dilated or incised with laser. Instilling contrast directly into excluded calyx with either CT or ultrasound guidance can be helpful in identifying the target. Another technique is directing percutaneous needle towards the ureteral catheter positioned in the most likely location for stenosed infundibulum. Once wire is passed into the renal pelvis, a neoinfundibulum is created, serially dilated and then stented [72].

### Potential complications

Complications are similar to those found with calyceal diverticulum treatment. Bleeding and re-stenosis are specific concerns. All efforts to avoid pulsatile vessels should be made at the time of the procedure.

### Outcomes

Data are limited to small case series with calyceal diverticulum patients in the mix. Of the reported series, the success rate is reasonable at 60–80% [63, 74, 75]. No treatment method has been evaluated extensively enough to recommend one surgical approach over another.

### Posttreatment evaluation

Since infundibular stenosis is rare, no clear standardized follow-up protocol exists. We stent the infundibulum (ureteral stent or percutaneous nephrostomy tube) for 4–6 weeks. Urine culture is checked prior to stent removal. If positive for infection, the patient is treated with antibiotics prior to drainage tube removal. Following tube removal, we perform a CT urogram at 4–6 weeks. If there is no evidence of recurrent stenosis, the patient is followed with annual ultrasound imaging.

## Symptomatic renal cysts

Simple renal cysts are noncommunicating fluid-filled structures arising from the renal parenchyma. The incidence increases with age; in one study by the age of 40 years 27% of adults had renal cysts, increasing to 61% by 80 years old [76]. They are occasionally caused by a genetic defect, such as autosomal dominant polycystic kidney disease. Renal cysts are generally asymptomatic and enlarge slowly, although in 2–4% of cases they can cause pain, compression of the collecting system (especially in parapelvic location), infection, or bleeding [77, 78]. Although an association between renal cyst disease and hypertension has previously been suggested, a study of 1526 consecutive patients argued otherwise [77, 79].

### Diagnosis

Simple renal cysts are almost always benign. Complex cysts can harbor malignancy. Although a simple cyst can be diagnosed with an ultrasound, any complex features require a contrast-enhanced CT or magnetic resonance imaging (MRI). The Bosniak classification is used to estimate malignancy risk (Table 28.1) [80]. An excretory CT urogram is useful if compression of the underlying collecting system is suspected. The differential diagnosis of a renal cyst includes calyceal diverticulum, hydrocalyx, UPJ obstruction, and a cystic renal mass. Scanning the patient in supine and prone positions helps differentiate a complex cyst from a calyceal diverticulum with calculi [3, 81], while delayed imaging demonstrating layering of contrast within a "cyst" defines calyceal diverticulum [15]. It is important to rule out malignancy before considering

**Table 28.1** Bosniak radiographic classification of renal cysts and risk of malignancy [80].

| Category | Description | Malignancy risk |
|---|---|---|
| I | Simple, thin walled without septa, calcifications, or solid components | <1%<br>No follow-up required |
| II | Does not enhance with contrast and measures such as water density | 3% |
| IIF | Thin-walled cyst with a few thin (<1 mm) septa with or without fine calcifications. Uniformly high-attenuation (>20 HU) lesions of <3 cm with sharp margins that do not enhance | 5–10%<br>Follow-up recommended |
| III | Multiple thin septa. Septa are thicker than hairline or slightly thick walled. Calcifications may be nodular and thick without contrast enhancement. No enhancing soft tissue elements | 40–60%<br>Surgical excision recommended |
| IV | Intrarenal non-enhancing high-attenuation renal lesions of ≥3 cm | >80%<br>Surgical excision recommended |

percutaneous treatment of a cyst, especially since a neoplasm is more likely to become symptomatic than a simple cyst [82].

### Treatment

Current treatment options include percutaneous aspiration with sclerotherapy, retrograde ureteroscopic puncture, percutaneous resection, and laparoscopic/robotic unroofing. Simple cyst drainage without sclerotherapy has a recurrence rate of 30–80% due to secretory epithelium lining the cyst [77]. Thus injection of a sclerosing agent (ethanol, polidocanol, tetracycline, povidone-iodine, and many others) is preferred, with 75–100% success rates [83, 84]. This procedure is well tolerated with minimal complications, although UPJ fibrosis due to sclerosant extravasation, cyst abscess, fever, pain, and recurrence have been reported [85, 86]. The optimal technique (ultrasound vs. CT guidance), number of treatment sessions, and choice of sclerosant are still being debated [77].

Retrograde ureteroscopic treatment with holmium:YAG laser unroofing and internal marsupialization is limited to parapelvic cysts adjacent to the collecting system. Yu et al. described cure in 26 out of 35 patients and Mao et al. described cyst reduction or elimination in 20 out of 21 patients with this approach [87, 88] with only 25 minutes operation time.

Laparoscopic unroofing is suited to any large renal cyst. A randomized trial of 40 patients revealed similar success of aspiration/sclerotherapy and laparoscopic unroofing despite laparoscopy being more invasive [89].

Percutaneous resection was first reported in 1984 [90]. Multiple follow-up series have confirmed the efficacy and safety of the procedure [84, 91–94]. It is particularly attractive if there are concomitant renal stones.

### Technique

The cyst is accessed using either ultrasound or fluoroscopic guidance. Retrograde installation of contrast allows fluoroscopic targeting, as the collecting system is distorted by the renal cyst. The cyst is accessed percutaneously with triangulation technique and fluid is aspirated to confirm intracyst positioning of the needle. The fluid is sent for cytology and culture. If there is any suspicion of malignancy a core biopsy of the cyst wall should be sent, since cytology alone has a false-negative rate in renal cell carcinoma [95]. Access to the cyst is then achieved in an identical fashion as for a calyceal diverticulum.

Once the access sheath is inside the cyst lumen, the entire cyst wall is examined and fulgurated with a rollerball electrode and 1.5% glycine irrigation fluid. Electrocautery should be set at the lowest possible settings to allow for blanching of the cyst wall without perforation [84]. Bipolar electrocautery with saline irrigant can be used with similar results [96]. A portion of the cyst wall is excised using grasping forceps or loop resection for marsupialization into the retroperitoneum. We do not routinely marsupialize to the collecting system since reports indicate recurrence rates are not decreased with this procedure [84, 97]. An 8 or 10 Fr locking Cope loop nephrostomy tube is left inside the cavity and removed the next day.

### Potential complications

In addition to typical percutaneous procedure risks, cyst recurrence or incomplete obliteration can occur.

### Outcomes

Although earlier studies reported 15–50% recurrence rate [91, 92], Shah et al. reported durable success in 8 patients with 5-year follow-up [97]. Chen et al. describe percutaneous marsupialization technique for renal cysts with ipsilateral renal calculi with no recurrence at mean follow-up of 22 months [93]. Busato and Bettega reported 100% success rate in 32 patients with mean follow-up of 76 months [94].

### Posttreatment evaluation

Although standardized follow-up recommendations do not exist, we perform a renal ultrasound and urinalysis three months post procedure. Since recurrence rates are so low, annual follow-up once cyst is resolved is not required [94].

## Conclusion

Percutaneous treatment of calyceal diverticula, infundibular stenosis, and symptomatic simple renal cysts is a safe and effective option in appropriately selected patients. Long-term data support the role of percutaneous treatment of calyceal diverticula as the initial intervention. Although studies on percutaneous treatment of hydrocalyx associated with infundibular stenosis and symptomatic renal cysts are limited, it remains a minimally invasive treatment option.

## Introduction

Percutaneous instillation of topical agents started when Crowell disintegrated a cystine stone by instillation of alkaline solution into the kidney [1]. Before the advent of miniaturized fiber-optic flexible ureteroscopes and nephroscopes, the nephrostomy tube provided a conduit for direct instillation of topical agents into the collecting system, thus minimizing systemic side-effects. Chemolytic agents for stones were the original and most common agents. Currently, there are two other categories of topical instillation agents used: chemotherapeutic/immunotherapeutic agents as adjuvant treatment for upper tract transitional cell carcinoma (UTTCC) and antifungal agents. The advantages of direct instillation when compared with systemic therapy include increased duration of direct contact of the topical agents with the collecting system, which allows topical agents reach the target organ in appropriate concentrations. This leads to shorter therapy and avoidance of harmful systemic side-effects [2]. In addition, these topical agents can be administered in patients with compromised renal function, inadequate urinary drainage, and high operative risk due to comorbidities [3]. However, it is important to note that there are several contraindications to initiating or continuing percutaneous instillation of topical agents. These include: positive urine culture, febrile patient, persistent flank pain, extravasation of irrigation fluid, or intrapelvic pressure >25 $cmH_2O$ [4].

With recent advances in endourologic technology, indications for instillation of topical agents have evolved and can be very useful for select patients. Although principles of instillation of topical agents into the collecting system are simple, minor errors in technique can result in catastrophic complications. Therefore, in addition to the urologist, both the nursing staff and the patient should be aware of the tell-tale signs of complications and should inform the treating physician immediately to stop the instillation. Therefore, urologists should be familiar with techniques of instillation, indications and contraindications, success rates, and any potential side-effects. In the present chapter, chemolytic agents (for stones), chemotherapeutic/immunotherapeutic agents for UTTCC, and antifungal agents will be reviewed.

## Techniques of irrigation/instillation

Topical instillation of agents into the collecting system depends on the principle of free flow of the solution throughout the collecting system, thus providing a continuous milieu of irrigant solution to the stone, UTTCC, or fungus ball. This can be achieved through several techniques: either retrograde fashion, percutaneous antegrade fashion, or a combination of both.

### Retrograde approach

The retrograde technique is the most simple and least invasive. It is done through a single ureteral catheter that is advanced beyond the level of the lesion or stone. The main disadvantage of this technique is the limitation of outflow through or around this small stent. This can result in a rapid elevation of intrapelvic pressures. Therefore, this technique of irrigation is not recommended. In an attempt to avoid this complication, Kuwahara and colleagues [5] used a computer-controlled, pressure-monitor intermittent pump (Figure 29.1a). This pump infuses fluid for 1 minute, holds for 30 seconds, and then drains for 9 seconds. If the pressure increases beyond the preset limit (15 $cmH_2O$), the infusion stops.

If the pressure increase is sustained for 5 seconds, the drainage valve opens. This system was not widely used because it was prohibitively expensive; because of this, its safety and efficiency were not properly evaluated. Without such a pump, a single ureteral catheter for irrigation is not recommended.

Several other techniques of retrograde instillation have been described. One technique proposed by Dormia et al. [6] utilizes concentric catheters placed in the ureter to facilitate the outflow from the kidney into the bladder (Figure 29.1b). Another less-efficient technique is by vesicoureteral reflux in a patient with an indwelling

ureteral stent after ureteral meatotomy [7]. Recently, a high-flow low-pressure irrigation system was described that uses an 8 Fr pigtail catheter through a 12/14 Fr ureteral access sheath (Applied Medical Systems, Rancho Santa Margarita, CA, USA). In an *in vitro* study, this system was found to be associated with significantly higher flow rates and lower pressures when compared with a single nephrostomy tube without ureteral catheters [8].

## Antegrade approach

The ideal inflow and outflow is achieved by percutaneous antegrade fashion through the use of two nephrostomy tubes. For example, two Malecot catheters (16 or 18 Fr) could be used (Figure 29.1c). This configuration is versatile and can be used in most patients. In patients with struvite stones, which tend to form large, irregular pieces on fragmentation, an endopyelotomy stent (14/8.2 Fr) provides excellent two-way outflow, decreases the volume of fragments that enter the ureter and prevent its obstruction [9] (Figure 29.1d). Another method of preventing ureteral obstruction is insertion of an indwelling double pigtail catheter when two Malecot nephrostomy tubes are used. A simpler method of inflow and outflow in antegrade fashion through two nephrostomy sites is the use of a circular tube (Figure 29.1e).

Two coaxial techniques of irrigation have been described. Hare and McOmish [10] described a renal pelvic lavage set to irrigate different areas of the pelvis through a single nephrostomy site allowing both inflow and outflow (Figure 29.1f). Once the Teflon sheath is in place, an inner 6.3 or 8.3 Fr pigtail catheter is directed at the stone for inflow. Outflow, which is limited, occurs through the surrounding sheath and down the ureter. The second coaxial technique of irrigation works well for upper ureteral stones [11, 12]. It is set up by inserting either a 5 Fr ureteral or angiogram catheter over a wire through the lumen of an 18 Fr Foley catheter, which serves as a nephrostomy tube (Figure 29.1 g). The small inner catheter, which provides inflow, can be advanced so that its tip is adjacent to the stone, whereas the Foley catheter provides outflow. This is an effective method for dissolving upper ureteral stones. A simpler technique of irrigating the renal pelvis through a single nephrostomy site is the use of a three-way Foley catheter [13].

## Combined approach

One combination of both antegrade and retrograde techniques can be accomplished through the insertion of a percutaneous nephrostomy (NT) tube and ureteral catheter. The NT acts as an ideal outflow while the ureteral catheter is used for instillation (Figure 29.1 h). However, using the combination of a ureteral catheter, a urethral catheter and a nephrostomy tube severely decreases patient mobility. Therefore, a modified approach can use an NT to instill agents and an indwelling double pigtail ureteral catheter as a drainage catheter. The drawback of this approach is that there is much less efficient outflow through a ureteral catheter than a nephrostomy tube. Therefore, this modification would be ideal for small stones that dissolve in a short period of time, such as uric acid stones.

All the techniques described above should follow appropriate safety principles. Patients should have preoperative urine cultures and be treated with culture-specific antibiotics. Urine cultures should be negative prior to initiating irrigation and patients should be kept on antibiotics throughout the irrigation. In addition, once the tubes are inserted, contrast studies should be performed 24 hours later to rule out extravasation. The irrigation should start slowly with warm saline at a rate of 30 ml/h. When the patient remains pain-free and afebrile, the rate is doubled every 2–4 hours until the target rate of 120 ml/h is reached [13]. After 12–24 hours of saline irrigation, the active agent is instilled at a rate of 30 ml/h and increased sequentially to 120 ml/h. There are several advantages to warming the irrigation solution. It is more comfortable for the patient, it avoids hypothermia, and it may increase the effectiveness of therapy [14–16].

It is important to have an intrapelvic pressure-monitoring system in all of the techniques described. If renal pelvic pressures are uncontrolled, pyelovenous and pyelolymphatic backflow leads to systemic absorption. Subsequently, the patient may suffer agent-specific systemic toxicities or changes in serum chemistries when the irrigant solution is nontoxic [17]. The intrapelvic pressure should not be allowed to rise above 25 $cmH_2O$ in order to prevent pyelovenous backflow [18]. The simplest method is the use of a central venous pressure (CVP) manometer connected to the inflow line. This is readily available and familiar to the nursing staff. Unfortunately, this is an open system that is prone to contamination or overflow spills. Furthermore, it requires continuous monitoring since there is no preset pressure alarm or automatic shutoff for high pressures (>15 $cmH_2O$). A better alternative is a closed continuous infusion pump that provides a continuous display of the intrapelvic pressure and will sound an alarm and shut off if the preset limit is exceeded (CareFusion, San Diego, CA, USA) [6]. Regardless of which pump is used, the patient should be taught how to immediately turn off the pump in case of flank pain or fever.

## New concepts

Small-caliber percutaneous instruments (SCPI) provide a new range of tools for kidney stone treatment. The impact of combined high-pressure irrigation inflow and simultaneous sensor-controlled suction on irrigation turnover and intrarenal pressure in SCPI was recently investigated. A 9.5 Fr Amplatz sheath was introduced through the lower calyx and an 8 Fr ureteric catheter was inserted through the ureter of a nonperfused porcine kidney. Another 8 Fr ureteric catheter was inserted through the upper calyx, and irrigation was performed using a pressure-controlled, combined irrigation/suction pump. Analysis of the intrapelvic pressure was performed by different irrigation pressures with and without sensor-controlled suction through the ureteric catheter [19]. After initiating irrigation flow, the intrarenal pressure reached a plateau within seconds without any pressure peaks during the whole experiment. This sensor-controlled suction increased fluid turnover and decreased intrarenal pressure in SCPI. In addition, such a purging effect prevented collapse or hyperdistention of the collecting system, especially in small-caliber instruments. However, SCPI has not been tested in humans yet.

Similarly, Colli et al. found that application of a 10 Fr ureteral dual-lumen catheter in a porcine model produced adequate retrograde drainage with low intrarenal pressures at high infusion rates (up to 80 ml/min) [20]. This experiment supports the use of separate channels for inflow and outflow during retrograde infusion to maintain intrarenal pressures around 5 $cmH_2O$.

Nakamura et al. reported a novel constant-pressure irrigation technique for a case of a left renal pelvic tumor which developed postradical cystectomy, right nephroureterectomy, and left ureterectomy in a patient with multiple urothelial tumors. The tumor was endoscopically ablated through a nephrostomy tract followed by mitomycin C irrigation [21]. The authors designed a novel constant-pressure irrigation system for effective and safe irrigation into the closed-space renal pelvis. Through a hole in the urinary drainage bag tube, a 5 Fr open-ended ureteral catheter was inserted, and the tip of the catheter was kept at the tip of the nephrostomy tube. The ureteral drainage tube was placed 20 cm above the kidney level to continuously irrigate the renal pelvis with mitomycin C for six-weekly treatments of 1 hour each time. The patient has been recurrence-free for one year (Figure 29.1i).

## Chemolysis of urinary calculi

Stone dissolution through chemolysis remains an option in the treatment of urolithiasis even with the advent of more sophisticated modalities. Chemolytic agents can achieve benefit through either primary or secondary dissolution. Primary dissolution is when chemolytic agents are used as initial therapy to dissolve stones completely or partially. This may be an option in patients unfit for general anesthesia. Secondary dissolution may be useful in patients with residual fragments after some other primary therapy. In this context chemolysis may render the patient stone-free, thus reducing the potential for recurrences or more invasive interventions.

For effective chemolysis, the irrigant and irrigation system must have several important characteristics. First, the irrigant must be compatible with biological tissue and be of limited toxicity. Second, it should have minimal systemic absorption in order to limit potential toxicity. Third, the irrigant should dissolve calculi and their fragments quickly to reduce treatment burden for the patient. Fourth, solutions used for irrigation must not precipitate, causing secondary stone formation. In addition, an ideal irrigation system must provide for free flow of irrigant to a targeted area, while maintaining low renal pelvic pressures to prevent bacteria from entering the bloodstream and to avoid renal damage [17].

Unfortunately, stone dissolution through chemolysis has several limitations. Some stones may require long treatment periods, which may necessitate prolonged hospital admission and patient discomfort. The efficacy of stone dissolution is dependent on many stone-specific factors. For example, uric acid and struvite amorphous minerals dissolve much faster than highly crystalline salts such as calcium oxalate. Likewise, stone size and shape will determine the rate of dissolution. Large stones will dissolve more slowly than the same volume of smaller stones because the surface area is greater in the latter [22, 23]. These variables can make it difficult to predict the necessary length of treatment a priori. In addition, the choice of chemolytic agent will depend on stone type. This requires that stone composition be determined prior to chemolysis. When stone fragments are not available, surrogate methods of determining stone composition, such as CT characteristics or the composition of previous stones, must be used to determine the agent of choice [17, 24, 25].

### Uric acid stones

Almost all individuals who form uric acid stones have persistently low urinary pH (<5.5) and most excrete normal amounts of uric acid [26, 27]. The acid–base properties of uric acid stones render them amenable to dissolution therapy. Uric acid is a weak organic acid with a $pK_a$ of 5.35 in urine at 37 °C. At this pH, half is present as the undissociated acid and half as the urate anion. Since urate is more soluble than uric acid, raising the urinary pH within the physiological range has a profound effect on how much uric acid/urate can be dissolved. For example, a urine sample containing 800 mg/l total urate will have 600 mg/l uric acid at a pH of 5.0 but less than 100 mg/l at pH 6.5. The latter figure is well below the solubility limit of uric acid so that a solution above pH 6.5

can dissolve a uric acid calculus [18]. Any solution above pH 7 is likely to be effective but higher urinary pH solutions may have a tendency to calcify the stone, particularly if sodium bicarbonate is used as the base [28]. Increasing the urinary volume further enhances the therapeutic efficacy of alkaline medications [29]. In addition, decreasing the oral purine load from dietary sources can effectively help treat patients because 40– 60% of excreted uric acid is derived from exogenous sources. Regardless of the method chosen, urine pH should be monitored with pH strips to optimize therapy. Serum and urine uric acid levels are also important to follow, especially in those with recurrent calculi.

To identify those most likely to respond to dissolution therapy, Reichard et al. found that patients with 100% uric acid stones were older, heavier, and had a higher serum uric acid level, and lower urinary pH than those with mixed stones, while urinary uric acid was not significantly different among groups [30]. However, it is unclear whether these characteristics alone will provide enough specificity to predict uric acid stones.

### Systemic agents

Systemic alkalinization is generally achieved with oral or intravenous therapy. The most popular agent is sodium bicarbonate, and the dose is 650–1000 mg three to four times daily. An alternative preparation, if the sodium load is too great, is potassium citrate administered as 15–30 mEq three to four times daily. Specifically, oral alkalization therapy for uric acid calculi has been established in the literature as an effective, totally noninvasive therapy [31]. It is generally effective for stones of 8–52 mm long with success rates of 62–72% in adults within six weeks to six months [32, 33]. Furthermore, oral alkalization is well tolerated and effective in children with uric acid stones, where it eliminates the need for shock-wave lithotripsy (SWL) in up to 73% of those children. One randomized controlled trial (RCT) showed comparable stone-free rates for dissolution therapy and a single session of SWL (72.9% vs. 82.1%, $P = 0.31$). Children undergoing dissolution therapy received potassium sodium hydrogen citrate at a dose of 1 mEq/kg per day for 1–3 months [34]. Several other oral therapies have been suggested to facilitate dissolution therapy. Sterrett and colleagues [35] demonstrated that acetazolamide, a carbonic anhydrase inhibitor, was effective in increasing the urinary pH in patients with uric acid and cystine stone formation who were already taking potassium citrate. Caution must be applied when prescribing acetazolamide, because it could be poorly tolerated and can induce calcium phosphate stone formation. A dose of 250–500 mg is taken at bedtime to maintain urine alkalinity during sleep. In cases of hyperuricosemia and hyperuricosuria, allopurinol should be added to inhibit the production of uric acid through inhibition of xanthine oxidase enzyme.

Intravenous alkalinization is more effective than the oral route. Urinary pH is elevated more quickly, to a higher degree, and is more reliable. This technique, however, is typically reserved for hospitalized patients with acute episodes of (renal) colic and obstruction. One-sixth molar lactate solution has been demonstrated to dissolve uric acid stones even when they are causing ureteral obstruction [36]. Lactated Ringer's solution with one to two ampoules of sodium bicarbonate added per liter is an acceptable alternative. The infusion rate (usually 50–100 ml/h) is titrated to a urinary pH of 7.0–7.5, which occurs within 4 hours. Cardiac and hypertensive patients must be monitored for the large sodium load in these solutions.

### Chemolytic agents

Since the urinary pH can usually be raised to at least 6.5 with oral or intravenous alkaline salts, medical therapy is ordinarily the treatment of choice for uric acid stones [18, 27, 29]. There are clinical situations in which oral or intravenous therapy is not possible, such as in patients who are noncompliant, or have chronic renal failure or an ileostomy. These patients may benefit from direct chemolytic therapy. Additionally, if a large amount of residual fragments is present after an initial therapy, direct chemolysis is a viable option.

The most common alkalinizing agents are sodium bicarbonate solution (pH 7.0–9.0), tromethamine (THAM, pH 8.6), and THAM-E (pH 10.5). Sodium bicarbonate solution is inexpensive and prepared easily by adding 2–4 ampoules (44 mEq each) to each liter of irrigant solution (normal saline solution or water). With this solution, there is no value in increasing the final urinary pH >7.5. In fact, higher elevations may be detrimental to stone dissolution because phosphatic and sodium urate encrustations may form a coating on stones [37]. The THAM solutions are more effective and do not cause such mineral deposits. It has been shown in animal models that THAM results in more rapid stone dissolution than sodium bicarbonate [28]. THAM-E is slightly more effective than THAM because of its higher pH but it is also responsible for more irritation and potential damage to the epithelium [38, 39]. Therefore, for uric acid chemolysis, THAM appears to be the agent of choice [18] (Table 29.1).

If a uric acid staghorn calculus is present, pretreatment with SWL may increase the stone surface area to facilitate dissolution. Unlike struvite and cystine stones, it is unusual to need prolonged irrigation to manage uric acid stones.

## Cystine stones

Cystinuria is an autosomal recessive disorder of dibasic amino acid transport in the kidney that leads to crystallization of poorly soluble cystine in the urine [51].

**Table 29.1** Results of direct chemolysis for uric acid and cystine stones.

Between 3% and 59% of those who are homozygous for the trait will produce stones [52]. The disease is more severe in men than in women in terms of early appearance and number of produced stones. Although the incidence of cystine stones is only about 0.9%, cystine stones rank third in terms of rate of recurrence [53]. Treatment of cystine stones continues to be one of the most challenging therapeutic dilemmas in endourology because of a high frequency of recurrence, resistance to SWL, difficulty in localization, and the insufficient effect of oral chemolysis [44].

Because of the difficulties in treating cystine stones, much emphasis has been placed on prophylaxis. The solubility of cystine, like all amino acids, is pH-dependent. Therefore, the production of alkaline urine can prevent cystine precipitation in the urine. A significant increase in cystine solubility begins to occur when urinary pH exceeds 7. For example, at a pH of 8, cystine solubility increases to approximately 1000 mg/l [54]. However, a significant drawback of urinary alkalinization is increased risk for calcium phosphate precipitation with pH above 7.5 [55]. For this reason, urinary pH of 7.5 is recommended [54]. It is recommended that this alkaline urinary pH must be maintained at night while the patient sleeps. The use of the potassium salts of citrate and bicarbonate may be more effective than the analogous sodium compounds because the presence of a sodium ion increases cystine excretion in the nephron. Because of this, a low-sodium diet may be useful in the management of cystinuria [56].

Cystine is composed of two cysteine molecules joined by a disulfide bond and its dissolution requires alkalinization and splitting of the disulfide bond. This can be accomplished through either oral therapy or direct chemolytic therapy. D-Penicillamine, the first oral agent used for cystine stones, is a disulfide exchange resin that facilitates separation at the disulfide bond through the thiol exchange reaction, forming mixed disulfides, and also decreases urinary excretion of cystine. The exchange reaction forms penicillamine disulfide–cysteine, which is 50 times more soluble than cystine [57] and is readily cleared through the urine. D-Penicillamine is administered as 1–2 g in four divided doses, starting with a small dose and increasing as tolerated. Side-effects of the drug include leukopenia, thrombocytopenia, gastrointestinal disturbances, skin rashes, proteinuria and nephrotic syndrome, neuropathies, and abnormalities of taste and smell. D-Penicillamine has been reported to dissolve even large stones when combined with alkalinization but its potential side-effects severely limit its usefulness.

α-Mercaptopropionylglycine (MPG) is another disulfide exchange resin with fewer side-effects than D-penicillamine and appears to be more effective [58]. The usual dose of MPG is 600–1800 mg daily in four divided doses. Simultaneous treatment with oral sodium bicarbonate increases the effectiveness of this preparation because the disulfide exchange reaction is more active at higher pH levels.

Oral acetylcysteine, MPG, and D-penicillamine are much more effective in preventing the formation of cystine calculi than dissolving them. When used for direct chemolysis, however, they are potent dissolution agents. During direct irrigation the solution bathing the stone will have a much higher concentration of the active agent. The pH of the solution is likewise more easily controlled, thereby facilitating the thiol exchange reaction [13].

Chemolysis monotherapy would require lengthy durations of irrigation for most stones. Approximately 9 days are required to dissolve a 1 cm cystine calculus. This irrigation time could be diminished when combined with SWL or percutaneous nephrolithotomy (PCNL), which reduce the stone burden and increase the surface area of the remaining fragments. Stones <1.5 cm may be treated initially with SWL since it increases the stone surface area and decreases dissolution time by nearly 50% [22]. If successful fragmentation occurs, repeat SWL or medical management may be sufficient as follow-up therapy. Otherwise chemolysis alone or combined with PCNL is appropriate. For stones >1.5 cm, PCNL is the initial procedure of choice. Residual calculi, which are likely to remain, can be effectively treated with chemolysis and additional PCNL or SWL sessions. Simultaneous oral therapy should be implemented in all cases [13] (Table 29.1).

If the stones appear extremely resistant to therapeutic measures, the possibility of a mixed stone should not be overlooked. Hydroxyapatite, struvite, calcium oxalate, and calcium phosphate contaminants have been found to be present in 14–46% of cystine calculi analyzed in some studies [59].

In summary, although cystine urinary calculi continue to present a formidable challenge to urologists, successful eradication without open surgery may be accomplished with chemolytic techniques in conjunction with minimally invasive fragmentation procedures.

## Struvite stones

Struvite stone formation typically occurs in patients with recurrent urinary tract infection and retained urine. Predisposing factors include urinary tract obstruction, chronic indwelling catheter, urinary diversion, and neurogenic voiding dysfunction [60]. Most commonly, staghorn stones are composed of a mixture of struvite (magnesium ammonium phosphate) and calcium carbonate apatite. In fact, hypercalciuric patients begin with calcium oxalate stone formation and develop superimposed infection with struvite deposition [61, 62]. Struvite calculi are typically referred to as "infection stones" because of their strong association with urinary tract infections caused by such bacteria. Silverman and Stamey [63] identified *Proteus* as the dominant microorganism in 72% of isolates from stone formers. Urease produced by such bacteria leads to hydrolysis of urea to ammonium, hydroxide, and bicarbonate, which increases the pH of the urine (pH >7.2). This alkaline urine, in the presence of trivalent phosphate, results in struvite crystal formation [64]. Other urease producers include *Klebsiella*, *Pseudomonas*, and *Staphylococcus* species [63, 65]. The most ubiquitous uropathogen, *Escherichia coli*, only rarely produces urease and thus is an infrequent cause of staghorn calculi [66].

Struvite stones are characterized by their large size and exceptionally rapid growth. It is not uncommon for a staghorn calculus to involve the entire renal pelvis and calices, nor for it to be formed within a four-week period [60].

Management of struvite stone disease is one of the most frustrating problems in urology as efforts to eradicate such stones often have suboptimal success rates. The problem is not only ridding the patient of the calculi but also sterilizing the urine. Persistence of infection was estimated to occur in approximately 40% and is believed to be responsible for many of the stone recurrences [67]. The presence of small stone particles with embedded bacteria serves as a nidus for new stone formation and rapid recurrences. Therefore, postoperative irrigation therapy has been proposed to potentially reduce struvite stone recurrences [68, 69]. Medical dissolution therapy for struvite and carbonate apatite stones has been described as a second-line treatment option. Oral chemolysis is available primarily in the form of urease inhibitors. Acetohydroxamic acid, the most commonly used agent, was identified as an irreversible urease inhibitor by Fishbein and Carbone [70]. The drug acts synergistically with several antibiotics, sterilizing the urine more rapidly, and its clinical usefulness has been demonstrated in double-blind studies, although serious side-effects precluded its use in patients even though they are reversible and dose-related [71–73]. The usual dose is 250 mg orally three times daily to be reduced to twice daily for mild renal impairment, and it is contraindicated in patients with severe renal insufficiency and in pregnancy. Most common side-effects reported were hemolytic anemia, neurosensory deficits, and thrombophlebitis. Headache, gastrointestinal upset, weakness, and flushing sensation after alcohol ingestion have also been reported [74]. Nevertheless, it is the only US Food and Drag Administration (FDA)-approved urease inhibitor available today [75].

Systemic oral chemolytic agents are seldom effective in reducing stone burden on their own and direct chemolysis of struvite calculi is a far more effective method of dissolution. Suby and colleagues [76, 77] presented the first application of direct chemolysis to struvite calculi where the initial solution was found to be too irritant for urothelium to be clinically used. Suby's solution G, formed by addition of magnesium to the previous formulation, has similar efficacy with decreased mucosal irritability (Table 29.2). Hemiacidrin (renacidin) is a multi-electrolyte solution introduced by Mulvany [78] by modification of Suby's solution. The acids present in this solution provide hydrogen ions and citrate to form soluble complexes with phosphate (phosphoric acid) and calcium (calcium citrate) from the stone (Table 29.3). Magnesium undergoes ion exchange with calcium present in the stone, enhancing dissolution while reducing irritation. The solubility of struvite is markedly increased at a pH <5.5, which occurs with each of the three variants of Suby's solution. This finding was confirmed in a recent *in vitro* study by Jacobs et al. [79]. The success rate of these medications in the literature has been reported to occur in the range of 68–80% [80].

Infectious complications are known to occur as a result of dissolution therapy. Renacidin and Suby's solutions have been implicated as the cause of urosepsis and death, and the FDA banned the use of renacidin irrigation for upper urinary tract stones on June 13, 1963 [90]. Urosepsis is thought to occur due to the release of large amounts of viable bacteria from stones as they dissolve. Therefore, it is critically important to stop treatment if fever occurs and until any infection has been adequately treated.

The presence of catheters and extensive use of antibiotics can also facilitate fungal infection. Replacing the irrigation fluid with amphotericin B (50 mg/500 ml $H_2O$) at a rate of 125 ml/h generally clears the funguria in less than 72 hours. Chemolysis irrigation can resume once urine cultures are negative for 24 hours.

## Calcium stones

Calcium-based calculi constitute about 80% of all urinary tract stone calculi of which about 80% are calcium oxalate stones [91], and yet they are the least amenable to chemolysis. The strong acids required to dissolve this compound cannot be safely used in humans. Only chelating agents have successfully been used *in vivo* to dissolve these types of stones. Ethylene-diamine-tetraacetic acid (EDTA) is the most commonly used solvent, and has shown moderate success in humans [92, 93] in spite of the significant urothelial injury reported [47]. EDTA is a polyvalent molecule which binds calcium through its two amine and four carboxyl groups. This sequestration dissolves the calcium component of the stone, thus reducing stone burden. Complete stone dissolution of over 50% in 260 patients treated with EDTA was reported [94]. Early use of this solution after stone formation is associated with a better response rate. These authors also used 0.25% lyophilized papain to dissolve the matrix component of stones. EDTA solutions are not widely used, primarily because they can cause urothelial injury.

In recent *in vitro* trials, mixed solutions containing natural and synthetic chelating reagents were found to be successful in dissolving calcium oxalate calculi. These solutions consisted of citrate and EDTA ions in addition to ampicillin sodium salt with a pH value of 6.4 [95]. This chemolytic solution seems to destroy oxalate/phosphate and pure phosphate stones including brushite stones. However, there are no reports of clinical studies using these solutions.

Oxalate-based stone dissolution using enzymes appears to be another viable option. Thalji et al. found that the addition of oxalate decarboxylase to calcium oxalate monohydrate crystals resulted in production of highly soluble calcium formate and a 15-fold increase in the solubility of calcium oxalate monohydrate. Moreover, adding formate dehydrogenase increased the dissolution 47-fold when compared with controls [96]. Lysine was also discovered to have a promising place among the major solvents of calcium oxalate stones. Its positive impact on calcium oxalate dissolution was related to lowering supersaturation of human urine [96]. Therefore, lysine injection could effectively prevent the formation or further development of calcium oxalate stones. Finally, both experimental and clinical studies of

hyperoxaluria-associated calcium oxalate kidney stone formers showed that oxalate-degrading microorganisms are capable of and important in regulating urinary oxalate levels. Preliminary experiments suggest that oxalate decarboxylase and oxalate oxidase can actively dissolve calcium oxalate crystals. Therefore, it seems reasonable to start using oxalate-degrading microorganisms with their free enzymes to enhance natural dissolution of calcium oxalate stones [97]. In the future, these manipulations may play a role in dissolution or prevention of calcium oxalate calculi, but they have not yet been proven in clinical practice.

## Summary

In summary, percutaneous chemolysis is an adjuvant treatment option for certain types of stones in highly selected cases. The choice of chemolytic agent and method of administration is dependent primarily on stone composition and should be tailored to the individual clinical scenario. There are several chemical means to increase the solubility of a stone. Manipulation of the pH is most commonly used. However, other modalities include disulfide rearrangement and cation chelation [18]. Manipulation of pH works particularly well for uric acid stones since they are 11 times more soluble at a pH of 6.5 than pH of 5.0 [27, 98]. An effective therapeutic pH of slightly above 7.0 can often be achieved with oral therapy alone but direct chemolysis should be considered for large stone burden [99]. Struvite stones will dissolve at pH of 4.9, but at a rate too slow to be clinically useful [100]. Therefore, other approaches, including systemic chemolysis with urease inhibitors or direct chemolysis with renacidin solution could be considered. The solubility of cystine is increased in alkaline urine, but is higher than that required to dissolve uric acid (pH of 7.5). At a pH of this range, there is an increased risk of secondary precipitation. Therefore, cystine stones can be more effectively treated with direct chemolysis using disulfide exchange resins. Calcium stones are the least amenable to chemolysis, but some success has been shown with EDTA chelation. However, toxicity to the urothelium limits the usefulness of this approach.

Finally, in a cost-conscious healthcare system with rising costs of hospitalization and limited inpatient beds, it is increasing difficult to admit patients for direct chemolysis of stones. Therefore, percutaneous chemolysis for dissolution of calculi is reserved for patients who are poor surgical candidates for minimally invasive endourologic procedures.

## Chemotherapy and immunotherapy for upper tract transitional cell carcinoma

UTTCC accounts for less than 5% of all urothelial cancers and 10% of renal tumors [101]. Nephroureterectomy with excision of a bladder cuff is the gold standard of care for UTTCC, especially for patients with high-grade, muscle-invasive, or multifocal disease with a normal contralateral kidney. Organ-preserving procedures that include ureteroscopic or percutaneous resection and segmental ureterectomy have been reserved typically for patients with solitary kidney, bilateral disease, poor renal function, small tumor burden, and low-grade disease [102]. The advent of improved endourologic techniques facilitates access to any part of the upper tract so that tumor location is no longer a limiting factor. Tumors such as large renal pelvic and proximal ureteral lesions which cannot be adequately treated with retrograde ureteroscopic approach can be resected percutaneously. Although endoscopic approaches for treatment of UTTCC have traditionally been reserved for patients with contraindications to nephroureterectomy, they could be offered to patients with low-grade solitary UTTCC lesions and normal contralateral kidneys [103].

Adjuvant topical immunotherapy or chemotherapy after endoscopic resection of UTTCC has been used in an attempt to reduce the risk of recurrence and progression. Bacillus Calmette–Guérin (BCG), mitomycin C, and thiotepa are the most common agents used. Their use as adjuvant topical agents has been extrapolated from their benefit in the management of superficial bladder transitional cell carcinoma. However, the role of these adjuvant topical agents for the treatment of UTTCC is not well defined [103].

There are several important considerations when using a topical chemotherapeutic agent rather than a chemolytic or antifungal agent. In terms of mode of instillation, the antegrade approach has been hypothesized to maximize contact of the agent with the urothelium and minimize contact interference between the agent and the retrograde ureteral stent [104]. However, this approach predisposes to the theoretical risk of nephrostomy tract seeding. Nevertheless, there are no available data to advocate one approach over another [105].

High pressures in the renal pelvis and extravasation after BCG application must be avoided. For the antegrade approach, the patency of the ureter to the bladder must be verified before each perfusion using contrast media. This also excludes any pyelovenous or pyelolymphatic backflow. If the nephrostomy tract was used for resection of the UTTCC, initiation of adjuvant BCG therapy is usually delayed for 2–3 weeks to allow for healing of the urothelium, thereby decreasing the risk of systemic side-effects. Furthermore, BCG must not be instilled in the presence of gross hematuria for fear of severe systemic complications.

Oosterlinka et al. described a method of instilling BCG in an antegrade fashion into the upper tract. A dose of 360 mg Immuno BCG Pasteur F (Institut Pasteur, Paris, France) or 243 mg ImmuCyst® (Sanofi Winthrop, Meyriez, Switzerland) is dissolved in 150 ml of normal saline. This is the same concentration but three times the dose and volume that is used intravesically. The flask is placed 20 cm above the level of the kidney of the supine patient. A continuous flow of approximately 1 ml/min (15–20 drops per min) is maintained for 2 hours [106]. After the perfusion is finished, the nephrostomy tube is clamped. Patients receive ampicillin prophylactically and are kept under hospital surveillance for one night. BCG instillations are repeated on a weekly basis for six weeks [107].

For the retrograde approach, it is advised not to use ureteral catheters larger than 5 Fr to allow drainage along the ureteral catheter to the bladder. It is very helpful to use fluoroscopy, at least for the first session, to establish proper catheter position and rule out unexpected anatomical difficulties. Free flow of urine from the catheter or retrograde injection of contrast verifies proper position in the collecting system. Ureteral catheters are secured via silk ties to a Foley catheter placed to drain the bladder and brought to rest at the bladder neck. The Foley catheter is either left to straight drainage or elevated over the bedrail to allow some collection into the bladder, depending on whether simultaneous bladder exposure is desired. It may also be capped during treatment if formal intravesical instillation is performed at the same time. The viscosity of the full-dose BCG suspension is such that it will not spontaneously drip under gravity instillation through such a small 4 Fr catheter. Therefore, low-dose BCG (one-third to one-tenth standard dose) plus interferon-α (50–100 million units) in 50 ml normal saline is used with the retrograde approach [102]. The patient is positioned supine and the medication is suspended in an intravenous bag no more than 30 cm above the kidney level. Medication is instilled via micro drip tubing at the rate of 1 drop per 2 seconds, corresponding to a rate of approximately 30 ml/h. The drug is only instilled via gravity and should never be placed on a pump for fear of increased intrarenal pressure. At the end of treatment, the Foley catheter is drained and then removed with the attached ureteral catheters.

A novel approach to gain upper tract BCG exposure was reported by Herr in a patient with grade 3 renal pelvic transitional cell carcinoma and carcinoma *in situ* in an ectopic solitary kidney [108]. After open surgical resection, a freely refluxing pyelovesical anastomosis was constructed. The patient received six-weekly intravesical instillations of BCG and subsequently remained recurrence-free at 13 months follow-up. Ramsey and Soloway [109] reported a similar approach accomplished by creating a freely refluxing system after autotransplantation of a solitary kidney with recurrent pyelocalyceal transitional cell carcinoma. For patients with refluxing urinary diversions, mitomycin C or BCG can be delivered via a catheter placed into the conduit or reservoir.

A substantial proportion of patients with endoscopically managed UTTCC will develop a recurrence. Adjuvant topical immunotherapy or chemotherapies have been used in an attempt to reduce the risk of tumor recurrence and are often reserved for patients with large, multifocal, or residual tumor. The true benefit of topical therapy, either as a primary treatment of carcinoma *in situ* or as adjuvant therapy for endoscopically treated UTTCC, is difficult to assess due to heterogeneous groups of patients receiving such therapy (solitary vs. multifocal disease, primary vs. recurrent, low- vs. high-grade) [102]. These retrospective case series are summarized in Table 29.4. Here we present the three most common agents used.

### Bacillus Calmette–Guérin (BCG)

BCG, a live attenuated strain of *Mycobacterium bovis*, first indicated as a tuberculosis vaccine, has had widespread use in intravesical immunotherapy since the 1970s [130]. It has since then become the drug of choice for treatment of carcinoma *in situ* in addition to being an effective prophylactic agent against recurrences following transurethral resection of high-grade superficial bladder tumor [131–133].

The mechanism of action has been intensively investigated. BCG directly binds to fibronectin within the urothelium, subsequently leading to direct stimulation of a cell-based immunologic response. Numerous cytokines involved in the initiation or maintenance of inflammatory processes, including tumor necrosis factor-α, granulocyte–macrophage colony-stimulating factor, interferon-γ, and interleukins are induced. This immunologic response activates cell-mediated cytotoxic mechanisms that are believed to underlie the efficacy of BCG in the prevention of recurrence and progression [134].

Most patients develop an inflammatory immunologic response to BCG during a typical induction course of six-weekly instillations. Optimal dosing and instillation schedules have not yet been established but some recent trials have demonstrated that a reduced dosing regimen (one-third dose) may be as effective as standard dosing but with fewer side-effects [135–137]. Studer et al. [107] first demonstrated the feasibility and efficacy of using BCG in the upper urinary tract. They treated 10 renal units that had cytologic evidence of carcinoma *in situ* with BCG delivered via a percutaneous nephrostomy tube. In seven of the ten renal units, urinary cytology reverted to negative. Although complications were few, BCG sepsis did develop in one patient, necessitating cessation of therapy. Since then, several other studies have demonstrated the safety and efficacy of intracavitary topical therapy in combination with endoscopic management in UTTCC as shown in Table 29.4 [103, 110–129, 138–142].

There have been no randomized trials comparing endoscopic treatment of UTTCC with or without BCG. Results achieved with intracavitary topical therapy have been varied. Although some authors found intracavitary topical therapy to be beneficial in terms of recurrence and disease-free survival, but not in overall survival, others found no benefit. In one of the largest series of adjuvant therapy for UTTCC, Thalmann et al. [103] retrospectively evaluated the results of BCG therapy in patients not eligible for nephroureterectomy. Thirty-seven patients (22 with carcinoma *in situ*, 15 with Ta or higher after endoscopic resection) were treated with six perfusions of BCG given once a week via a 10 Fr nephrostomy tube. At a median follow-up of 42 months, 14 patients (38%) died of urothelial cancer, 11 (29%) of other causes, and 12 (33%) were alive. Other adverse outcomes included severe septicemia in 2 patients. There was no seeding of the nephrostomy tube tract and dialysis was avoided. Overall median survival was 42 months (range 1–137 months) with median recurrence-free survival of

21 months (range 1–137 months). The authors noted that this was a patient population with a poor prognosis, and while BCG extended survival for some patients, it did not provide cure except for some patients with carcinoma *in situ*. Of the patients treated in the adjuvant setting for papillary disease, only 13% remained without recurrent or progressive disease with a median time of recurrence of 10 months. In contrast, treatment of carcinoma *in situ* resulted in 32% of renal units remaining disease-free for a median follow-up of 51 months.

A recent update of this retrospective series with 64 renal units and a median follow-up of 42 months (range: 2–237) showed recurrence of UTTCC in 30 of 64 renal units (47%), including 17 of 42 (40%) patients with Tis and 13 of 22 (59%) patients with Ta/T1 tumors [123]. There was progression of UTTCC in 11 of 64 renal units (17%), 2 of 42 (5%) patients with Tis and 9 of 22 (41%) patients with Ta/T1 tumors. Nephroureterectomy was performed eventually in 7 of 64 renal units (11%), 2 of 42 (5%) with Tis and 5 of 22 (23%) with Ta/T1 tumors. Not surprisingly, patients with Tis had better recurrence-free survival ($P = 0.42$) and significantly better progression-free survival ($P; < 0.01$) and nephroureterectomy-free survival ($P = 0.05$) when compared with patients with Ta/T1 tumors [123]. Since this study did not include any controls, it could not determine whether intrarenal instillation of BCG was associated with any survival advantage.

Orihuela and Smith [139] found a recurrence rate of 80% among patients who did not receive supplemental BCG versus a recurrence rate of 16.6% among those who did. However, an update of their series could not ultimately demonstrate a survival advantage with the addition of adjuvant BCG [111]. Rastinehad et al. [122] retrospectively studied 133 renal units treated by percutaneous resection for UTTCC. Eighty-nine renal units treated primarily by percutaneous resection were then analyzed. Fifty renal units received adjuvant BCG therapy two weeks after endoscopic management for a total of six courses. Recurrence was defined as a positive biopsy result after the third-look nephroscopy. Overall median follow-up was 40.8 months. There was no statistical difference with regard to tumor grade or stage between treated and nontreated groups. Recurrence, time to recurrence, and progression of disease among renal units treated with BCG were subselected by grade and compared with the corresponding nontreated group. There was no statistical significance demonstrated between any of the treated and nontreated groups. The authors concluded that there is no overall oncologic benefit in the administration of adjuvant BCG with regard to disease recurrence, interval to recurrence, and progression of disease in the treatment of UTTCC. The latest analysis of this retrospective series from Smith's group included 141 patients with median follow-up of 66 months [143]. Nephroureterectomy was avoided in 87% of patients. Recurrence occurred in 37% of low-grade UTTCC patients and 63% of high-grade UTTCC patients, with a median time to recurrence of 71.4 versus 36.4 months, respectively. On multivariate analysis, grade was the only predictor of recurrence (HR 2.12, $P = 0.018$). Disease in one patient recurred after 116 months of surveillance, emphasizing the importance of long-term follow-up after endoscopic management of UTTCC. Similar to their previous analysis, BCG and mitomycin did not protect against recurrence, progression to nephroureterectomy, or death over resection alone [143].

Similarly, Martinez-Pineiro et al. [114] have shown reduction in recurrence rates with addition of BCG or mitomycin C following endoscopic treatment of UTTCC. The authors reported a recurrence rate of 50% among patients with grade 2 or 3 disease who were not treated with adjuvant therapy, versus a recurrence rate of 27.7% among a similar group of patients who received some form of adjuvant therapy. They used several drugs in that study, including BCG, mitomycin C, 5-fluorouracil, thiotepa, and interferon-α, from which only BCG and mitomycin C were promising. Finally, Katz et al. [121] published their initial experience with BCG plus interferon-α2b. With a median follow-up of 24 months, 80% demonstrated a complete response, while 20% had a partial response (decrease in tumor size, number, or both). The authors reported that the treatment was well tolerated in the office setting and did not note any complications.

In contrast, other studies have not shown a significant difference between patients treated with adjuvant mitomycin C or BCG compared to those undergoing endoscopic treatment alone [112, 144]. Hayashida et al. [145] reported a 50% disease recurrence rate after a follow-up of 50.9 months using intrarenal perfusion of BCG with endoscopic treatment. This high recurrence rate occurred despite an initial return of cytology results to normal and all of these patients suffered cancer-specific mortality.

There are several known complications of cavitary BCG therapy. Persistent fever after BCG administration has been reported in 3 out of 59 (5.1%) patients in a combined series. However, this resolved in all cases with appropriate antimicrobial therapy [111, 114, 144]. Granulomatous involvement of the upper urinary tract may occur in up to 25% of patients after BCG administration [146]. Therefore, it is important to obtain percutaneous biopsy of renal masses that develop in patients who have received intracavitary BCG prior to deciding on their management [147]. In addition, these renal granulomas could be observed in asymptomatic patients and they may resolve without antituberculous medications [147].

The controversy and variability among studies addressing intracavitary use of BCG as an adjuvant therapy for UTTCC are likely the result of lack of prospective randomized studies and reliance on retrospective case series with their inherent biases in patient selection. Some authors treat all patients with adjuvant therapy while others treat only high-risk patients. Furthermore, it is important to note that there are several products containing different substrains of BCG. There is variability of BCG organisms per milligram of vaccine with different substrains and variability from lot to lot within the same substrain [148, 149]. Thus, the true efficacy of adjuvant BCG therapy for UTTCC has yet to be adequately evaluated. However, secondary effects of therapy seem to be generally well tolerated among patients.

## Mitomycin C

Less information is available on the use of intracavitary mitomycin C topical treatment compared with BCG. Mitomycin C is a 334 kDa alkylating agent that inhibits DNA synthesis. Because of its moderately high molecular weight, there are few problems with transurothelial absorption. Therefore, side-effects such as myelosuppression are rare with mitomycin C. The typical dosage varies from 20 to 60 mg per instillation, and the most commonly used dose is 40 mg in 40 ml of saline or sterile water administered weekly for eight weeks.

Keeley and Bagley [124] reported on adjuvant mitomycin C (40 mg in three divided doses via ureteral catheter) in 19 patients (21 renal units) for high-volume, recurrent or multifocal urothelial carcinoma. No systemic side-effects occurred during or after treatment with mitomycin C. Thirty-five percent had a complete response, 27% had a partial response (reduction in tumor size >50%), and 38% had no response. Tumors with a complete response were of similar size and grade as those that did not respond as well. After a mean follow-up of 30 months, none of the patients suffered local disease progression or died of disease; however, nearly all of the patients required repeat ureteroscopic treatment for residual or recurrent disease. At least one case has been reported of toxic agranulocytosis following absorption of extravasated mitomycin C [114].

An alternative experimental treatment regimen for UTTCC in refractory patients is sequential gemcitabine and mitomycin C. Medication dosage is 1 g gemcitabine in 50 ml phosphate-buffered normal saline, then 40 mg mitomycin C in 40 ml of sterile water. The gemcitabine is instilled followed by mitomycin C immediately afterward. In a group of patients with treatment-refractory non-muscle-invasive bladder cancer, 8 of 37 had upper tract involvement. Gemcitabine alone was effective in only 1 of 14 patients (7%) while sequential treatment with gemcitabine followed by mitomycin C was successful in 13 of 23 patients (57%) [150]. The rationale for sequential treatment is that gemcitabine is too acidic and affects mitomycin C activity if given together. In addition, gemcitabine primarily kills cells undergoing DNA synthesis (S-phase) while mitomycin C is non-cell phase-specific and leads to cell cycle arrest. Gemcitabine is given first followed by mitomycin C to maximize therapeutic efficacy. Some authors feel that improvement of outcome can be achieved by overnight fasting, and the use of sodium bicarbonate to reduce drug degradation, and an increased concentration to 40 mg in 20 ml [151].

### Thiotepa

Thiotepa (triethylenethiophosphoramide) is an alkylating agent and is not cell cycle specific. Introduced in 1961, thiotepa is the oldest and one of the least expensive of the intravesical drugs. Doses range from 30 to 60 mg in 30–60 ml of sterile water or saline. The lower dose appeared to be as effective as the higher one in a comparative study when the concentrations were the same [152]. The Medical Research Council Working Party on Urological Cancer reported that the lower concentration of 30 mg in 50 ml was not effective [153]. The usual regimen consists of six to eight weekly instillations. A low molecular weight of 189 kDa allows partial absorption through the urothelium with possible systemic toxicity. Myelosuppression is a risk, especially with the 60 mg dose. Complete blood count is obtained before each instillation and treatment is delayed if necessary. Thiotepa is evaluated much less than other topical agents as adjuvant therapy after endoscopic management of UTTCC [112, 114].

### Summary

Of interest, renal function was not impaired after instillations of either BCG or mitomycin C. In most cases, the adverse events which could result from administration of such immunotherapy or chemotherapy can be avoided by maintaining low intrapelvic pressures during administration. Although the cumulative experience appears encouraging regarding the efficacy of topical immunotherapy, especially against carcinoma *in situ*, no individual study has shown statistical improvement in relation to survival. This could be the result of insufficient numbers of patients to examine the clinical significance of the drug and inadequate delivery of the drugs in adequate concentrations over a proper period of time to enable a clinical response when compared with lower tract transitional cell carcinoma [7]. There is no doubt that larger prospective studies are needed to settle this issue. It is apparent that most published series regarding percutaneous adjuvant therapy suffer from selection bias secondary to their retrospective design and involve few patients with short follow-up, making it difficult to reach any meaningful conclusion. As yet, no study has shown statistical improvement regarding survival and no protocol of treatment has been accepted. None of the published series have evaluated the role of maintenance therapy, likely because of access problems. Randomized multicenter trials are needed to evaluate the role of adjuvant topical therapy.

## Antifungal therapy

Upper urinary tract fungal infections are rare and are usually associated with diabetes, chronic renal failure, long-term antibiotic usage, immunosuppression, and terminal malignancy. Diagnosis is based on microscopic examination of urine and specific fungal culture. Histopathological examination of fungal balls will demonstrate the fungus. Recently, polymerase chain reaction has been used to detect candidemia in patients with candiduria and to detect candiduria before the culture reports are available [154, 155]. Opportunistic pathogens such as *Candida*, *Aspergillus*, *Mucor*, *Cryptococcus*, and *Histoplasma* are particularly known to infect the kidneys in predisposed individuals with serious complications. These infections are often insidious, and their diagnosis is usually delayed because of the coexisting illnesses [156, 157]. Renal involvement by fungi has been found to be associated with increased morbidity and mortality, particularly in cases of infections by angioinvasive fungi such as *Aspergillus* and *Mucor* [158–160].

Fungal infection may be systemic with secondary involvement of the urinary system or may originate in the urinary tract and then disseminate hematogenously. The use of an indwelling urethral catheter and administration of multiple antibiotics increases the risk of dissemination of urinary fungal infections [161]. These infections of the urinary tract must be diagnosed quickly and treated aggressively. If these infections are improperly treated, they can cause urinary obstruction through formation of accretions called fungal balls [162–164]. Fungal balls cause hydronephrosis, oliguria or even anuria, destruction of renal parenchyma, widespread dissemination of the organism, and death of the patient [165].

Percutaneous antifungal irrigation permits administration of highly toxic antifungal drugs to patients with localized infection, thereby minimizing systemic side-effects [166, 167]. Systemic antifungal agents have been successfully used but in the presence of an obstructed kidney due to extensive fungal infection, drainage of the pelvicalyceal system is mandatory to salvage the kidney. Amphotericin B and its formulations, the azoles (fluconazole, itraconazole, voriconazole, and ketoconazole), caspofungin, and flucytosine are used to treat urinary fungal infections. Schelenz and Ross [2] reported that intravenous antifungal drugs (e.g. caspofungin or amphotericin B) are useful in treating or preventing candidemia during instrumentation such as insertion of nephrostomy tubes in cases of *Candida* pyonephrosis. However, they are unlikely to lead to cure if used as the sole treatment. Conservative management should also include local drainage of pus and fungi as well as instillation of an effective antifungal agent.

The present discussion is limited to the major drugs used as topical urinary antifungals, namely fluconazole and amphotericin B. It should be remembered that fungal infections involving the genitourinary tract are frequently a part of multiorgan systemic disease, often involving an immunocompromised host.

## Fluconazole

Fluconazole is a triazole antifungal agent that is less toxic and more efficient than other imidazole members; it is safe in infants and children. The drug inhibits the cytochrome P-450 enzyme responsible for conversion of lanosterol to ergosterol, which is the major sterol of most fungal cell membranes. Fluconazole is highly water soluble and can be administered intravenously or orally. It is cleared primarily by renal excretion, with approximately 80% of the dose excreted as unchanged drug [168]. Fluconazole administered by mouth or by intravenous route achieves high urine levels [169]. In general, the drug is safe and well tolerated, even in very large doses. The most common adverse reactions are gastrointestinal disturbances.

Systemic fluconazole therapy can be effective in treating candiduria. In one series, orally administered fluconazole (100 mg twice daily for 10 days) eradicated candiduria in 19 of 20 critically ill patients, which was comparable to amphotericin B bladder irrigations [170, 171]. It is important to note that an elevated serum creatinine value is associated with a reduced rate of fungal eradication from the urine with systemic fluconazole therapy. This is likely related to lower urinary levels of fluconazole in patients with reduced renal function [172]. Therefore, in patients with renal impairment direct irrigation may be more effective at treating candiduria.

Fluconazole used as a genitourinary irrigant has been reported as an effective antifungal bladder irrigant [173]. Percutaneous fluconazole irrigation was successfully used to treat candidiasis in nephrostomy tubes that was unresponsive to systemic intravenous form [167]. Fluconazole solution was used as an antifungal irrigant in 20 patients with nephrostomy tube or suprapubic catheter who presented with two positive urine cultures for *Candida*. In 17 patients (85%), *Candida* was eradicated from the urine by the third to sixth day of irrigation. No side-effects were noted [174].

## Amphotericin B

Amphotericin B was first isolated as a byproduct resulting from the fermentation process of *Streptomyces nodosus* and is a member of the polyene macrolide class of antibiotics [175]. Depending on the drug concentration and susceptibility of the organism, amphotericin B may be either fungistatic or fungicidal. It binds to the sterol ergosterol that is present in the cell wall of susceptible fungi, leading to an alteration of the cell wall permeability and thereby causing leakage of cell components, with subsequent cell death. Oxidation-dependent amphotericin B-induced stimulation of macrophages of the host cells also may contribute to its antifungal properties [176]. Amphotericin B deoxycholate has been used in the treatment of most of the fungal infections, with nephrotoxicity being the most common serious chronic adverse effect [177]. Fortunately, this azotemia is usually reversible and sodium loading with intravenous saline and hydration may prevent or reduce the severity of the nephrotoxicity.

In an effort to reduce systemic side-effects, new formulations of amphotericin B have been developed. These formulations encapsulate amphotericin B in lipid vehicles, which are taken up by the reticulo-endothelial system concentrated in liposomes. Monocytes/macrophages in the peripheral blood are thought to take up the drug-laden liposomes and move them to the site of infection. Once these lipid complexes reach the site of action, free active drug is thought to be released through the action of phosolipases [168].

Bladder irrigation with amphotericin B is widely used and has become a standard treatment, although it has not undergone controlled trials [175, 178–182]. Tuon et al. [183] found that amphotericin B bladder irrigation (ABBI) showed a higher clearance of the candiduria 24 hours after the end of therapy than fluconazole. This was confirmed by fungal culture five days after the end of both therapies. The evaluation of ABBI using an intermittent or continuous system of delivery showed an early candiduria clearance (24 hours after therapy) of 80% and 82%, respectively. The use of continuous ABBI for more than five days showed a better result (88% vs. 78%) but this was not statistically significant. Although ABBI has been used in clinical practice, its use is not standardized, and some authors question whether ABBIs have any diagnostic or therapeutic value [184]. Others have advocated that amphotericin B no longer be used in the management of candiduria [170]. Removal of the urinary catheter, if possible, is more beneficial for the patient than instillation of bladder irrigation with amphotericin B [185].

In cases of pyonephrosis, the insertion of a nephrostomy tube for direct irrigation allows urinary diversion with subsequent improvement in renal function and enables the local administration of an antifungal drug directly to the site of infection [186]. Schelenz and Ross [2] demonstrated the limitation of intravenous antifungal agents such as caspofungin as the sole treatment of an obstructive upper urinary tract infection due to *Candida* species. In order to achieve long-term sustained cure from an obstructive pyonephrosis, pus and fungal balls should be drained and an antifungal agent such as amphotericin B deoxycholate instilled locally. An important issue in the management of pyonephrosis caused by such infections is the accumulation of pus and fungi in an obstructed space, such as the renal pelvices. As with other enclosed bacterial infections such as empyemas, drainage of the pus is of fundamental importance and may explain why systemic treatment with antifungals such as amphotericin B, caspofungin, or fluconazole alone have proven to be unsuccessful [167, 187]. Watson et al. [188] reported advantages of percutaneous upper urinary tract drainage as a potentially lifesaving adjunct in the treatment of pyonephrosis. Several case studies highlight the advantage of this maneuver in difficult cases involving obstruction due to extensive fungus.

Bartone et al. [189] reported on five neonates with obstructive urinary tract candidiasis in whom nephrostomy tubes had a major role in management. Eleven nephrostomy tubes were placed in seven patients (two neonates and five adults) who were identified to have renal fungal infections [186]. The nephrostomy tubes allowed prompt microbiologic diagnosis of fungal infection (*Candida albicans* in six patients; *Torulopsis glabrata* in one); urinary diversion with subsequent improvement in renal function, enabling systemic administration of potentially toxic antifungal drugs such as 5-fluorocytosine and amphotericin B (four patients); local irrigation with amphotericin B (four patients); guidewire fragmentation of fungus balls (two patients); and introduction of a Simpson atherectomy device to obtain biopsy specimens from an obstructing ureteral polypoid lesion (one patient).

Untreated or neglected candidiasis may progress to fungus ball or abscess formation. Sonography is commonly used as the initial imaging procedure but retrograde and antegrade pyelographies are used for biopsy, diagnosis, and treatment [190]. The advantages of nephrostomy tubes in this setting include prompt drainage of the obstruction, direct access to obtain specimens from the renal pelvis to confirm the diagnosis, direct irrigation of the fungus balls with amphotericin B, and an access route for fragmentation of fungus balls by guidewire manipulation [186]. Placement of nephrostomy tubes with antegrade amphotericin B irrigation, coupled with systemic antifungal therapy, is the mainstay of treatment for pyonephrosis.

Streptokinase has also been used in conjunction with amphotericin B in the treatment of pyonephrosis. Hutton [191] reported a problematic case in which a very low birth weight infant with obstructing ureteropelvic junction fungal balls that was refractory to standard measures of adequate nephrostomy tube drainage, pelvic irrigation with amphotericin B, and systemic antifungal treatment. In an attempt to avoid potentially difficult open surgery, the author used streptokinase solution (3000 IU/ml) for irrigation. This was successful in clearing the fungal balls, relieving obstruction and rendering the urine sterile. This case highlighted the potential role for streptokinase in cases of renal candidiasis refractory to current treatment protocols.

The role of antifungal agents for upper tract fungal infections will require ongoing investigation. However the relative rarity of this condition may preclude randomized trials. In cases of pyonephrosis the most reported approaches include placement of a nephrostomy tube and local instillation of an antifungal agent such as amphotericin B. The advantage of topical intracavitary treatment is that highly toxic medications can be delivered to the site of infection rather than systemically, which can minimize potential side-effects.

## Conclusions

Percutaneous therapy delivers medications or chemotherapeutics directly into the collecting system and can be highly effective at targeting the pathology. Direct therapy allows high local concentrations to be delivered while avoiding potential systemic complications. Stone dissolution through chemolysis remains an option for patients with multiple comorbidities and high surgical risk for minimally invasive endourologic procedures. Chemolysis is most useful for the treatment of uric acid stones when oral medical therapy is not feasible in the context of a patient who is noncompliant or cannot tolerate oral sodium or potassium salts. Direct chemolysis can also be used for dissolution of cystine and struvite stones. There is no clinically useful irrigant for dissolving calcium oxalate calculi. Chemolytic solutions may be used as primary therapy or as adjuncts to endourologic procedures. Intracavitary immunotherapy/chemotherapy is a useful adjuvant therapy following endoscopic management of noninvasive UTTCC with acceptable side-effects, but no individual study has shown statistical improvement with relation to survival. Percutaneous instillation of topical antifungal agents such as amphotericin B permits administration of highly toxic antifungal drugs to patients with localized infection, thereby minimizing systemic side-effects.

# Percutaneous Treatment of Ureteropelvic Junction Obstruction

*Michael W. Sourial,[1] Bodo E. Knudsen,[1] & Paul J. Van Cangh[2]*

*[1] Department of Urology, The Ohio State University Wexner Medical Center, Columbus, OH, USA*

## Introduction

Percutaneous endopyelotomy was one of the first minimally invasive surgical procedures to address a reconstructive operation. In patients with ureteropelvic junction (UPJ) obstruction the ultimate goal remains the relief of the obstruction in order to preserve renal function and reduce pain with minimal morbidity. Prior to the introduction of laparoscopic pyeloplasty, percutaneous endopyelotomy rapidly gained acceptance and became widely adopted in the management of UPJ obstruction, replacing open pyeloplasty [1].

However, being totally *endo*scopic, endopyelotomy can only address intrinsic factors of obstruction; extrinsic causes cannot be corrected. In UPJ obstruction, the renal pelvis is usually dilated or redundant. Classically, the volume should be reduced by resecting part of the wall, but this is not possible with a purely endoscopic procedure, neither redundancy of the renal pelvis. This probably explains its inferior success rate compared to pyeloplasty, especially when it is applied without selection [2–5]. As with many pioneering techniques, endopyelotomy has been superseded by newer techniques and is now less often performed (see Prognostic factors, patient selection, and results) [6–8]. It nevertheless retains its status as a landmark procedure, and could be regarded as one of the first natural orifice transluminal endoscopic surgeries (NOTES) to be routinely performed [7].

## Preoperative management

Preoperative evaluation of UPJ obstruction is mandatory with a view to documenting the following critical prognostic factors: the stricture (length, nature, and degree), the involved renoureteral unit (individual renal function, degree of hydronephrosis, remaining ureter), the presence of extrinsic factors (crossing vessels, bands), and the patient themselves (Box 30.1, Figure 30.1).

### Preoperative drainage

Preoperative decompression of the collecting system is advisable in totally obstructed cases, in case of active infection, or when there is a need to evaluate the function of the kidney. Tubular function recuperates in 10–15 days; glomerular function improves more slowly (up to three months). Despite its potential associated morbidity, we favor a small nephrostomy tube inserted under local anesthesia rather than a double-J stent, which commonly induces an inflammatory reaction at the UPJ that may later interfere with healing.

## Antegrade endopyelotomy

### Percutaneous endopyelotomy

For percutaneous endopyelotomy we start with the patient positioned prone in a split-legged position. A flexible cystoscopy is passed through the urethra into the bladder and a hydrophilic tipped guidewire is advanced up the affected side into the kidney. The cystoscope is then removed and a 5 Fr open-ended catheter is advanced up into the renal pelvis and secured. A 16 Fr Foley catheter is placed into the bladder. If this maneuver fails, the endoscopic route should be abandoned, since further attempts to localize an impassable UPJ usually are unsuccessful and an unguided incision is dangerous and may result in total separation of the ureter.

If the catheter is placed with the patient in the supine position, then they should be repositioned prone on the

table as for a classical percutaneous procedure Ideally, a posterior calyx is punctured and catheterized. A middle or superior calyx should be selected to secure an adequate working angle to the UPJ. The tract is dilated and the nephroscope is introduced. Secondary calculi are fragmented and extracted at this stage. The UPJ is easily identified by the protruding retrograde ureteral catheter. A second guidewire is introduced from above and down into the ureter. Streem describes placing the ureteral stent in an antegrade fashion prior to performing the incision using an acorn-tip Bugbee. The UPJ and proximal ureter can often be seen to bulge into the renal pelvis, such that a subsequent endopyelotomy is equivalent to a ureteral meatotomy at the ureterovesical junction. Having a stent in place at the onset of the procedure helps to better define the UPJ, and also obviates concern about avulsing the UPJ during placement of a stent after the UPJ has been incised [9] (see Video 30.1).

The best orientation for the incision is still a matter of debate. In a primary UPJ obstruction with no prior pyeloplasty, a lateral incision is made to avoid both a potential posterior and anterior crossing vessel [10]. In a patient who underwent a prior pyeloplasty and had a posterior crossing vessel displaced anteriorly, we prefer to make the incision posterolaterally. The incision is made through the entire thickness of the pelvic wall, the UPJ, and the narrow portion of the proximal ureter, and as far down as necessary to visualize a normal-caliber lumen, essentially performing an endoureteropyelotomy. A significant advantage of the direct percutaneous approach is the possibility of careful visual inspection of the pelvic wall, looking for pulsation transmitted from significant adjacent crossing vessels.

The second guidewire is advantageous to straighten and stiffen the ureter to be incised. Incision of the UPJ can be performed using a cold (straight or hooked) knife railroaded on the track, electric incision, or, more recently, the holmium laser. Equal success has been obtained with these different modalities. When the exact length of the abnormal ureter is in doubt, a dilation balloon is inserted

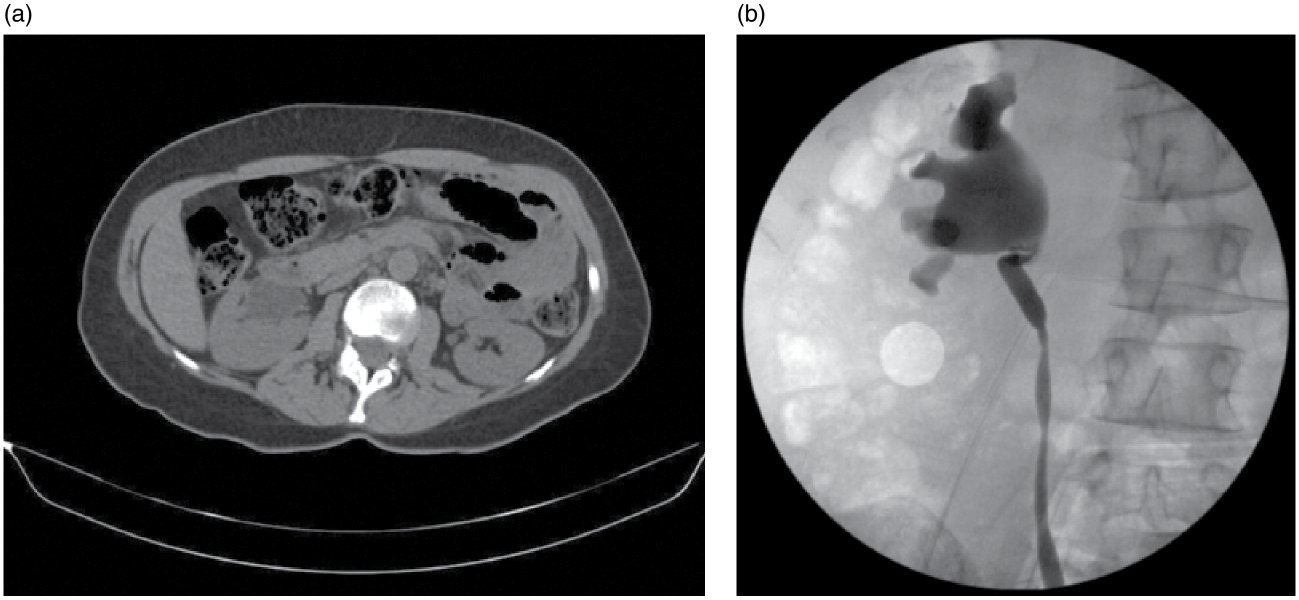

**Figure 30.1** (a) CT scan and (b) retrograde pyelogram showing right-sided hydronephrosis secondary to UPJ obstruction.

over the second guidewire and is inflated with contrast under fluoroscopic control, with care being taken to correct any residual or additional narrowed areas.

Prolonged stenting and drainage are deemed essential, although their exact duration is still a matter of controversy. A convenient drainage system consists of a 14/7 double-J stent, commonly referred today as an "endopyelotomy" stent (Figure 30.2), straddling the incised UPJ. Other drainage techniques including the traditional 8 Fr double-J stent have been used successfully, provided that extravasation is minimal and drainage is adequate. Our own practice has been to leave two traditional 7 Fr stents in parallel in an effort both to hold the UPJ widely open during the healing process and to provide maximum drainage. We typically do not leave a nephrostomy tube but a Foley catheter is placed to prevent reflux and further extravasation of urine through the endopyelotomy incision. In patients with a history of voiding dysfuction or a history of lower urinary tract symptoms, consideration to discharging them home with a Foley cather is made. The internal stent is removed under local anesthesia in the outpatient clinic after 4–6 weeks [1, 11, 12].

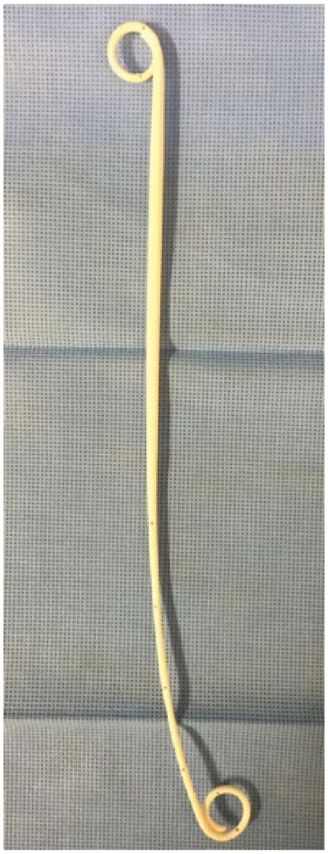

**Figure 30.2** Endopyelotomy stent. The proximal end measures 14 Fr and the distal end measures 7 Fr in diameter.

### Invagination technique

A safe UPJ incision may be facilitated by the modified technique described by Gelet and colleagues. Instead of using a simple open-ended ureteral catheter for the initial retrograde UPJ catheterization, a dilation balloon is used and inflated below the UPJ. After percutaneous access has been obtained, the inflated balloon is grasped from above and pulled inside the renal pelvis, invaginating the UPJ and proximal ureter. Using the holmium laser or a small electrocautery electrode, the double tissue layer (pelvis and ureter) is incised from inside the renal pelvis, down to the plastic balloon. If residual or additional narrowing is suspected, the balloon is reinflated on its way out to calibrate the ureter. When the balloon is deflated and removed from below, spontaneous reduction of the invagination occurs. Drainage and stenting are as in the procedure described earlier.

The invagination technique allows easier incision of the UPJ as the tissue is stabilized on the dilated balloon. It also reduces the risk of damaging crossing vessels, although such complications have occurred [13]. Few series have been reported in the literature, and this technique has unfortunately fallen out of favor to other more commonly practiced techniques.

## Endopyeloplasty

This ingenious procedure is a combination of endopyelotomy and pyeloplasty. Using a custom-made suturing device, a standard vertical endopyelotomy incision is sutured transversely (Heinecke–Miculikz principle). Its primary aim is healing of the endopyelotomy incision by primary intention with accurate suturing, minimizing fibrosis by avoiding urinary extravasation. Preliminary results for this nondismembered procedure appear promising. A totally dismembered procedure using the same suturing technique has been investigated. A feasibility study using a conventional suture with a lengthened 3.5 mm pediatric laparoscopic needle holder via the nephroscope was performed in 10 consecutive patients with promising results [14]. Unfortunately, these original series have not been duplicated, and to our knowledge endopyeloplasty is rarely performed [15, 16].

## Retrograde endopyelotomy

In order to further reduce the morbidity of the procedure, purely retrograde approaches have been devised. They share the advantage of avoiding percutaneous access to the kidney, decreased operative time, hospitalization, and patient morbidity. Modalities used to incise the UPJ include cold-knife, electrocautery, or, more recently, the holmium laser (Figure 30.3). Some of the limitations of retrograde endopyelotomy include difficulty inspecting for pulsation of crossing vessels, or the lack of direct visual control necessary for an exact incision in simple fluoroscopically guided cases [12]. With refinement in this technique over the years, this has become a widely established treatment option for UPJ obstruction [17].

## Ureterorenoscopic approach

In this technique a small-caliber ureterorenoscope is advanced up to the level of the UPJ and a lateral incision is performed under direct vision. The procedure may be facilitated by the preliminary insertion of a double-J stent, which then remains in place for 8–10 days. This maneuver, however, adds to the complexity of this technically difficult procedure, especially in muscular male patients. Most authors recommend the use of the flexible ureterorenoscope combined with the holmium laser. Although patient selection is a critical factor for the success of this technique, in experienced hands, success rates can be as high as 90% [17].

## Balloon dilation and rupture (“endoburst”)

A retrograde ureteropyelogram delineates the upper collecting system. A 24–30 Fr angioplasty balloon is inserted over a guidewire and positioned across the UPJ under fluoroscopic control. The balloon is inflated until wasting completely disappears. Several inflation/deflection cycles are recommended in order to ensure that no residual narrowing remains. An endopyelotomy stent is inserted over the initial guidewire. With few exceptions, long-term success with this technique has been inferior to that with incisional techniques [18, 19]. In a recent study by Xu et al. comparing retrograde balloon dilatation and

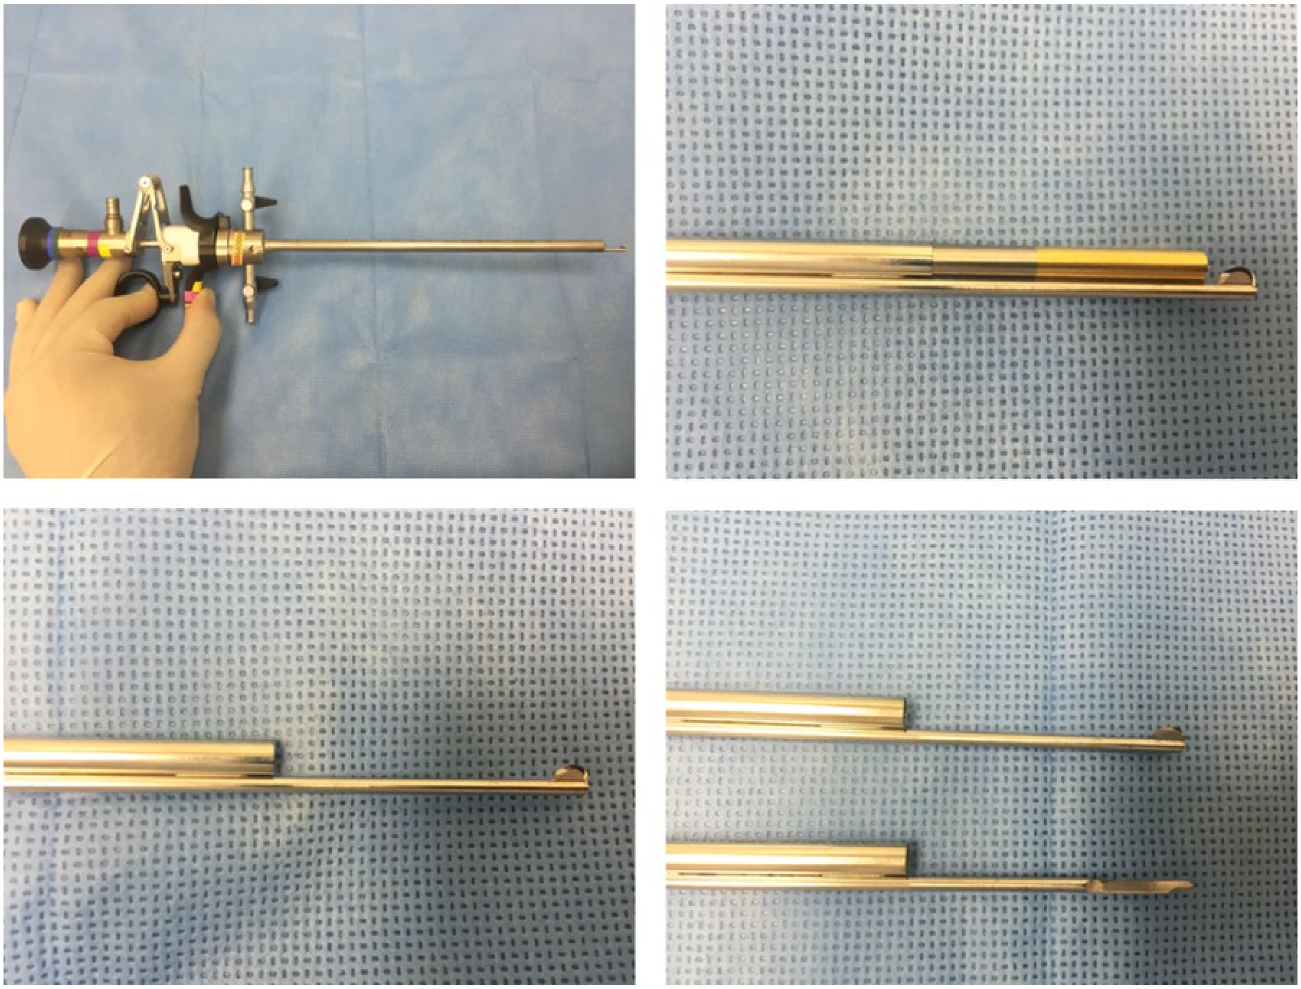

**Figure 30.3** Endopyelotomy using cold-knife. Various blades are available for the incision.

laparoscopic pyeloplasty for the treatment of UPJ obstruction, the 2-year success rate of laparoscopic pyeloplasty was 95.5%, compared to 71% for balloon dilatation alone. The authors recommended balloon dilatation for select patients as a method that is less costly, simpler, and easier to perform [20]. This technique can also be done in concert with an endopyelotomy incision.

### Balloon electrocautery incision: Acucise® endopyelotomy

The Acucise device is a 6 Fr catheter driving a 10/24 Fr low-pressure balloon fitted with an electrosurgical wire active over the 3 cm expendable portion of the balloon. The operative technique is similar to the one described earlier, except that the UPJ is not forcefully disrupted but cleanly cut by the electrosurgical wire that is activated during inflation of the balloon. Extravasation of contrast indicates that the incision has been completed. If there is doubt, flexible ureteroscopy and additional electrosurgical or laser incision under direct vision are recommended. The technique is safe and reliable, especially when the surrounding vascular anatomy of the UPJ has been ascertained by an appropriate imaging study [21]. Although initial results seemed promising [17], success rates in more recent series have been reported to be modest at best [22, 23].

## Laparoscopic and robotic pyeloplasty

The combination of laparoscopic and robotic pyeloplasty adds together the advantages of minimally invasive surgery (reduced morbidity) and open surgery (possibility to correct anatomic factors such as extrinsic obstruction, crossing vessels, and renal pelvis redundancy), and for many it has become the new gold standard. Both intraperitoneal and extraperitoneal approaches have been successful in achieving this goal. Laparoscopic pyeloplasty remains a difficult procedure, requiring considerable expertise; it is difficult to learn and to teach [7, 24]. The recent advance in robot-assisted procedures, albeit still costly, has increased the interest in this approach. Advantages include a shorter learning curve and greater ease of performing the anastomosis with wristed instrumentation and 3D visualization. Several series have reported a marked increase in the number of robotic pyeloplasties performed over the past decade [25, 26]. Today laparoscopic or robot-assisted laparoscopic pyeloplasty has become the procedure of choice for primary UPJ obstruction.

## Prognostic factors, patient selection, and results (Table 30.1)

Results for endopyelotomy fall somewhat short of those for contemporary pyeloplasty (67–95% vs. 95–100%) [3, 5]. As most endopyelotomy series using different techniques report approximately the same results, it is likely that selection criteria play a major role. Risk factors have been identified: the presence of vessels directly crossing the UPJ stands out as a major prognostic factor of outcome; a high degree of hydronephrosis or severely redundant pelvis; type of obstruction (length >2 cm); and renal function <25–30% [27, 28]. In such cases, laparoscopic or robotic pyeloplasty is preferred over endopyelotomy. Long avascular strictures and major alteration of renal function clearly contraindicate the procedure.

Several series have looked at the long-term outcomes of endopyelotomy. Knudsen et al. reported a success rate of 65 and 74% in primary and secondary UPJ obstruction, respectively, treated by antegrade endopyelotomy at a mean follow-up of 55 months. This group highlighted the need for long-term follow-up to identify late failures [29]. Although most failures will present within the first 20 months, late failures are not infrequent but do tend to stabilize after the fifth year [30, 31]. To demonstrate the importance of selection criteria, Butani and Eshghi performed a retrograde cold-knife endopyelotomy in 155 patients with strict inclusion

**Table 30.1** Therapeutic options for ureteropelvic junction obstruction.

criteria (stricture length <2 cm, absence of severe hydronephrosis, renal function >25%), and reported a success rate of 96% and 85% for primary and secondary procedure, respectively, at a mean follow-up of 60 months [32]. These criteria likely play a major role in success rates of endopyelotomy.

In our view, now commonly shared but still debated, the presence of significant crossing vessels should be ascertained preoperatively as it significantly influences the outcome. Modern imaging techniques, such as spiral computed tomography (CT), color Doppler, and endoluminal ultrasonography, have replaced the older, more invasive procedures. When a significant crossing vessel has been documented, a classical endopyelotomy is likely to provide inferior results, especially in the presence of a large renal pelvis. When a small artery or a venous channel is encountered, consideration can be given to transection of the crossing vessel [11, 12]. If a major vessel is present, an alternative treatment such as open or laparoscopic/robotic pyeloplasty is preferable. When renal function is poor (<10%), laparoscopic nephrectomy is the first choice.

Today, the major indications for percutaneous endopyelotomy are the combined treatment of UPJ obstruction and concomitant pathology, the most common being secondary renal calculi and secondary UPJ obstruction [8]. This is particularly true in cases where the crossing vessel or fibrous band was addressed at the initial laparoscopic or robotic pyeloplasty. Although several series have reported superior success rates with secondary pyeloplasty compared to endopyelotomy [33, 34], endopyelotomy remains a feasible, less invasive, and effective option in properly selected patients [35]. In addition, several centers with expertise in the procedure continue to recommend the operation in carefully selected patients with primary UPJ obstruction.

## Conclusions

Percutaneous endopyelotomy stands out as a landmark procedure, opening the way to reconstructive NOTES procedures. Like the majority of pioneering techniques, it has now been superseded by newer developments. Nevertheless, it retains specific indications, such as secondary UPJ obstruction and combined treatment of UPJ obstruction and associated anomalies.

# Percutaneous Management of Upper Tract Urothelial Carcinoma

*Shu Pan & Piruz Motamedinia*

*Department of Urology, Yale University, New Haven, CT, USA*

## Introduction

Upper tract urothelial carcinoma (UTUC) is a rare urologic malignancy with an incidence of one to two patients per 100 000 individuals annually. The average age of presentation is around the eighth decade of life, and about 60% of patients have invasive disease at presentation, in stark contrast to the 15–20% of those diagnosed with bladder cancer [1]. Historically, preoperative staging of UTUC depended on cross-sectional imaging and the use of tumor grade as a surrogate, since ureteroscopic biopsies often provided inadequate tissue sampling [2, 3].

Given the advanced stage at presentation, radical nephroureterectomy (RNU) with an ipsilateral bladder cuff excision is the gold standard treatment for UTUC [1]. Radical excision as a cure, however, may be more debilitating than the disease for patients with low-risk characteristics. Moreover, there tends to be multiple competing medical comorbidities in this patient population. RNU has been shown to increase cardiac events [4], significantly reduce renal function [5, 6], and potentially exclude patients from platinum-based chemotherapy, which is treatment necessary for the management of advanced urothelial carcinoma [7]. This presents one of the great challenges in managing UTUC – balancing the morbidity of treatment with acceptable oncologic outcomes.

The endoscopic approach for nephron-sparing management (NSM) is gaining acceptance for appropriately selected patients [8]. Patient selection requires parallel risk stratification of the patient's malignancy balanced with their comorbidities to provide the best outcome. Studies comparing endoscopic UTUC resection against RNU show no difference in overall survival [9], and similar cancer-specific survival in patients with noninvasive low-grade disease [10]. Renal preservation rates of 67–100% are observed, depending on the imperative indication for endoscopic management [8].

In this chapter we discuss patient selection for NSM in the treatment of UTUC, basic considerations/techniques in the percutaneous management of UTUC, and the subsequent long-term follow-up regimen.

## Patient selection

Indications for NSM of UTUC fall into two categories: imperative and elective (Box 31.1). Imperative indications for a minimally invasive approach include an anatomic or functionally solitary kidney, significant renal impairment, bilateral malignancy, and poor candidacy for radical surgery. Although cancer cure may be achieved, these patients would presumably fare worse with radical nephroureterectomy due to their underlying medical comorbidities or resulting renal insufficiency. End-stage renal disease requiring renal replacement therapy (hemodialysis) may significantly reduce life expectancy [11], and is associated with a poor quality of life [12]. Historically, candidacy for NSM was reserved for patients with imperative indications. However, similar to the advent of partial nephrectomy for renal cell carcinoma, improved risk stratification of UTUC has helped identify a cohort of patients who would benefit from elective NSM with comparable oncologic control and preserved renal function.

Elective endoscopic management relies heavily on preoperative risk stratification and patient selection. Traditional staging of UTUC on endoscopic biopsy is poor due to the limited depth of tissue procured, which understages a tumor in up to 54% of cases [2, 3]. The use of larger caliber biopsy forceps (e.g. BIGopsy back-loading biopsy forceps; Cook Medical, Bloomington, IN,

**Elective indications**

- Low-risk UTUC
- Highly selected high-risk UTUC: multifocal, large tumors, with low grade and superficial features

USA) or a basket snare can improve tissue yield and diagnostic accuracy [13]. The thin mucosa, lamina propria and muscularis layers of the ureter and renal pelvis still pose diagnostic challenges. Rouprêt et al. proposed a divergent scheme from classic TNM staging to risk-stratify patients and assess eligibility for NSM [14] (Table 31.1). They identified low grade on biopsy/cytology, noninvasive features on cross-sectional imaging, unifocal disease, and tumor size <1 cm as criteria for low-risk disease. High-grade features on biopsy or cytology, large or multifocal tumors, and hydronephrosis were criteria for higher risk disease inappropriate for elective endoscopic management in patients otherwise eligible for nephroureterectomy.

Unlike tumor stage, clinical grade is more accurately obtained through conventional ureteroscopic biopsies. Yamany et al. showed that ureteroscopic biopsy accurately graded 82% of patients, with 1.3% being downgraded and 16.7% upgraded on final nephroureterectomy pathology [3]. However, only one-third of patients were accurately staged, with nearly two-thirds being upstaged on final pathology, most commonly to pT2 or greater. Up to two-thirds of patients with high-grade disease on biopsy will have muscle-invasive disease [15]. High-grade disease has also been associated with an increased risk of recurrence (HR 2.12, $P = 0.018$) and lower overall survival (42% vs. 69.2% for low-grade disease) in patients undergoing NSM [16, 17]. Likewise, the negative predictive value of a low-grade tumor for the absence of muscle-invasive disease on final pathology is 72% [15]. Given the relative reliability of biopsy grade over stage and the clinical significance of grade as predictive of final pathology, high-grade disease should be the strongest factor of NSM ineligibility.

**Table 31.1** Risk stratification of upper tract urothelial carcinoma.

| Low-risk UTUC | High-risk UTUC |
|---|---|
| Low-grade biopsy | Hydronephrosis |
| Low-grade cytology | High-grade |
| Tumor <1 cm | Tumor >1 cm |
| No invasive features on imaging | Invasive features on imaging |
| Unifocal disease | Multifocal disease |
| Close follow-up possible and acceptable to patient | Failed previous endoscopic treatment |

*Source:* Adapted from Rouprêt et al. (2014) [14].

Tumor multifocality has been associated with poorer outcomes in patients undergoing RNU and long considered a high-risk characteristic in UTUC [18–21]. Interestingly, others have not been able to reproduce these findings in patients specifically undergoing endoscopic management [16]. Multifocality likely represents a predilection for cancer recurrence (pan-urothelial disease) and a greater tumor burden to be managed endoscopically. Multifocality should be considered in the context of endoscopic feasibility and surgeon comfort level rather than an absolute contraindication for endoscopic management. Likewise, tumor size should be given similar consideration. A solitary, low-grade, renal pelvis tumor over 1 cm may be beyond the capabilities of ureteroscopic management but easily accessible and resectable through a percutaneous approach. Rapid recurrence in the setting of multifocal or large tumor volume should still encourage RNU in surgically eligible patients.

Cross-sectional imaging, preferably with contrast urography, provides useful clinical data. Tumor size and location are often identified, which are invaluable for surgical planning. Furthermore, evidence of invasive or infiltrative disease raises concerns for advanced stage, thus discouraging primary endoscopic management. Hydronephrosis is also an independent predictor of high-grade advanced stage (≥pT2), non-organ-confined disease, as well as lymphovascular invasion [22–24]. The mechanism of hydronephrosis is not wholly elucidated but in most cases a result of bulky intraluminal disease. In more advanced cases, mural invasion and narrowing of luminal diameter may be an additional and more ominous etiology.

Lastly, the patient's compliance to a regimented follow-up schedule should be assessed prior to pursuing endoscopic management [25]. Patients treated with endoscopic NSM will need frequent surveillance of their upper tracts, in the form of repeat ureteroscopy under anesthesia and radiographic studies. An unwillingness or inability to comply should be considered against the option of NSM. In describing their institutional 30-year experience with endoscopic UTUC management, Motamedinia et al. described a patient with a primary recurrence 116 months following initial diagnosis. Although a complete resection and durable response is possible, recurrence is common and disease progression needs to be detected early to allow for potentially curative intervention [16]. Similar to bladder cancer, interval visual inspections of the urothelial lining are essential. Office-based or conscious ureteroscopy, although previously described [26], may not be practical or tolerable in all cases.

## Percutaneous tumor resection

Endoscopic management of UTUC is most commonly performed in retrograde fashion via a flexible ureteroscope and most small, low-grade tumors are readily accessible and appropriately managed through ureteroscopy. We have been able to push the envelope with the endoscopic management of UTUC through advancements in digital imaging and improved flexibility of small-caliber ureteroscopes. Modern ureteroscopes and a retrograde intrarenal approach are the workhorse for the visual diagnosis, initial tumor biopsy, and subsequent extirpation of amenable upper tract lesions. However, just as ureteroscopy has limitations in the management of large or complex upper tract stones, the same is true for renal pelvic, calyceal, and selective proximal ureteral tumors. Small-caliber biopsy forceps, snares, and lasers have a limited capacity for tumors greater than 1 cm or those involving a wide "carpeting" of urothelium.

The percutaneous approach for the management UTUC is not common, but is ideally suited for specific clinical situations. Percutaneous intrarenal access allows for the use of larger caliber instruments via a nephroscope, and even a resectoscope with cutting current loop. Higher volume irrigation coupled with suction devices can improve visualization and allow for a more complete resection. Percutaneous access is also favored for patients who have undergone cystectomy, especially with a continent urinary diversion, which would further complicate a retrograde approach.

Presurgical planning for percutaneous access is paramount. A preoperative CT urogram (delayed intravenous contrast phase) or magnetic resonance urogram illustrates the intrarenal anatomy, relative location of the tumor within the kidney, and facilitates the selection of a point of entry. In addition, it rules out invasive disease or nodal involvement, which would disqualify further endoscopic management. We favor a prone percutaneous approach under fluoroscopic guidance as this is also our preferred approach for percutaneous nephrolithotomy (PCNL). However, those who are more comfortable with supine PCNL or ultrasound-guided access should proceed accordingly. A posterior calyx containing a tumor should be directly accessed. If a tumor is located in an anterior calyx, direct access may be more challenging and thus an upper or lower pole puncture may allow for better trajectory into the calyx of interest. Tumors in the renal pelvis or proximal ureter should be approached through an upper or middle pole calyx when feasible, which offers a more direct angle of approach to the ureteropelvic junction. The calyx allowing for the shortest tract will also allow for maximal intrarenal maneuverability with a rigid nephroscope, especially in obese patients or in the setting of large and multifocal tumors.

Dilation of the nephrostomy tract can be performed with coaxial balloon dilation or serial renal dilators. Similar to PCNL, direct access into the renal pelvis should also be avoided due to the proximity of hilar vessels and the propensity for significant hemorrhage [27]. Should the puncture and subsequent dilation cause significant bleeding, the surgeon may consider placing a nephrostomy tube to tamponade the bleeding and to promote tract maturation. A repeat procedure may be conducted at a later date. In addition, great care should be taken to avoid perforation due to theoretical tumor seeding and retroperitoneal fluid collection. Ideal placement of the nephrostomy sheath is at the edge of the entry calyx to allow for complete visualization of the urothelium and reduce the risk of a missed tumor behind the sheath.

Once nephrostomy access tract is established and an assessment of tumor location is completed, we initiate tumor resection. An added benefit of the percutaneous approach is that a standard resectoscope with a monopolar or bipolar cutting loop or rollerball can be used through the percutaneous tract (Figure 31.1). Bipolar

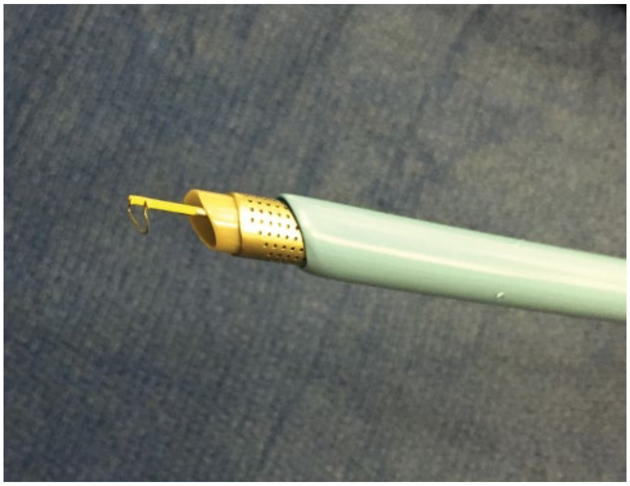

**Figure 31.1** Standard resectoscope (26 Fr) through a 30 Fr nephrostomy access sheath.

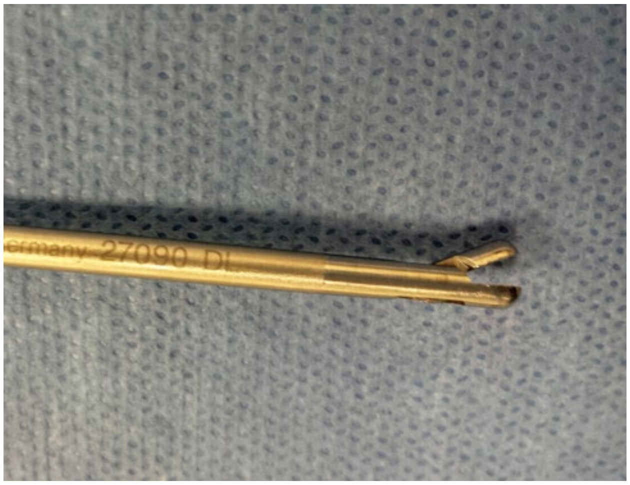

**Figure 31.2** Cold cup biopsy forceps.

energy with saline irrigation eliminates the risk of electrolyte abnormalities associated with the excessive hypotonic fluid absorption possible with monopolar resection. We prefer to first debulk the tumor with cold cup biopsy forceps, especially for papillary neoplasms (Figure 31.2). This allows for tumor removal without cautery artifact. There is also less risk of inadvertent perforation of the collecting system compared to a resectoscope loop when maneuvering in a confined space or approaching a bulky tumor. As the tumor is debulked and larger stalk vessels are exposed, interval hemostasis is necessary to maintain visualization. Our practice is to procure a separate specimen from the tumor base to aid in more accurate pathologic staging, as lamina propria or muscle invasion can best be demonstrated at this level. Careful resection is crucial as the infundibulopelvic urothelium lacks significant muscular backing and can easily be perforated. In addition, second- and third-order renal vasculature branches run parallel to the infundibula.

Use of lasers is also an option. Once the bulk of the tumor has been removed, neodymium:YAG or holmium:YAG lasers can be utilized to ablate the bases. Neodymium:YAG laser with its greater depth of penetration may be useful after a substantial resection as it can induce noncontact coagulation. Holmium:YAG laser with a depth of penetration of 0.4 mm will be inadequate in achieving hemostasis for larger bleeding vessels and has a tendency to accumulate tissue on the fiber tip [27].

In the event of significant bleeding following a deep resection or ablation, continued tissue fulguration or coagulation may be futile and only exacerbate further hemorrhage. A preferred maneuver would be to place a nephrostomy catheter with a balloon to tamponade the site. The procedure should be terminated with a plan for second look after about 48 hours.

The risks for percutaneous UTUC resection are similar to those for PCNL, including: infection, bleeding, collecting system perforation, hemothorax/hydrothorax for supracostal access, and rarely injury to the liver, spleen, or bowel. Risk of bleeding may be higher than that for conventional PCNL given the neoplastic vascularization and need to resect and ablate urothelium as a goal of the procedure. Historic studies have quoted transfusion requirements of 20–50% and vascular complications that correlate to tumor grade [28, 29]. Concern for tumor seeding along the tract is raised as a concern unique to percutaneous management of UTUC. However, only rare case reports have been published on this unlikely complication [30–32]. With appropriate patient selection, percutaneous resection of urothelial carcinoma remains a safe and effective treatment.

## Long-term follow-up

Following percutaneous intervention, in particular bulky tumors, “second look” nephroscopy may be performed two days after to eradicate any residual tumor burden [33]. Second look may be performed during the same hospitalization through the established nephrostomy tract, since matured. Repeat procedures usually afford better visualization and improved hemostasis. In addition to assessing for complete resection of the initial tumor, we advise inspection of the urothelium at the site of access to detect tumors that may have been obscured by bleeding of puncture and dilation. In addition, flexible nephroscopy should be utilized to revisualize all calyces, the renal pelvis, and the proximal ureter for potential missed lesions.

If pathologic analysis of the tissue returns as high grade or presence of muscle invasion, the patient should be counselled toward definitive management with nephroureterectomy. For patients with appropriately low-risk disease, an endoscopic surveillance should be planned within three months. A retrograde ureteroscopic approach is preferred as it is less invasive and is performed in an ambulatory setting. It also provides great flexibility to survey all calyces and allows for concomitant evaluation of the bladder and ureter.

There are no established guidelines for long-term upper tract surveillance following endoscopic resection. Our preferred regimen mirrors the surveillance guidelines for high-risk non-muscle-invasive bladder cancer established by the American Urological Association and Society of Urologic Oncology [34]. Patients undergo endoscopic evaluation (cystoscopy with ipsilateral ureteroscopy) every three months for the first 2 years and every six months thereafter. If the patient is free of recurrence for 5 years, surveillance is performed annually. Urine cytology is checked at each intervention. Cross-sectional imaging with contrast urography is performed annually. For patients with renal insufficiency precluding contrast enhancement, retrograde pyelogram is performed; however, this elevates the risk of missing extraluminal disease [35].

There are no strong data supporting a benefit from intraluminal bacillus Calmette–Guérin (BCG) following UTUC resection [16, 17, 36, 37]. Results utilizing BCG in patients with carcinoma in situ of the upper tract are more promising [37–39]. Ultimately, there are no randomized trials to prospectively quantify potential benefits in either scenario.

## Conclusion

Radical nephroureterectomy remains the gold standard treatment for patient with moderate- to high-risk UTUC. However, strong consideration for renal preservation should be given to patients with low-risk disease, regardless of medical fitness for radical surgery. A percutaneous approach to UTUC resection is ideally suited for calyceal and renal pelvis tumors, or patients who have undergone previous urinary diversion. A stringent follow-up regimen consisting of endoscopic surveillance and cross-sectional imaging is a vital part of endoscopic NSM and should be discussed between patient and practitioner.

## Part 7 Exit Strategy and Complications

# 32

# The Access-related Complications of Percutaneous Nephrolithotomy

*Vinaya Vasudevan, Zeph Okeke, & Arthur D. Smith*

*The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## Introduction

Percutaneous nephrolithotomy carries a stone-free rate of over 90%; however, the rate of Clavien I–II complications is almost double those for ureteroscopy and extracorporeal shock-wave lithotripsy (ESWL), at approximately 20% [1, 2]. The rate of Clavien III–IV complications is significantly lower, at a rate of 3.2–3.7% for major complications. Every urologist must be well versed in complications, as the rate of complications has been shown to exponentially decrease with experience [3, 4]. Patients with increasingly complex stones are also significantly more likely to experience a Clavien II–III complication [2]. Of note, patients with morbid obesity, a branched collecting system, spinal deformities, malrotated kidneys, horseshoe kidneys, and a large or complex stone are known to be at increased risk.

Prevention of complications is a complex issue. The astute surgeon should take the following steps prior to every surgery:

- Ensure that anticoagulants are held for the appropriate interval prior to surgery. Aspirin should never be held prior to surgery (Table 32.1).
- Ensure that the patient has adequate imaging for selection of the best access to maximize intraoperative stone removal. This means that the access tract will accommodate stone extraction from the other calyces as well.
- Ensure that the patient has sterile urine prior the procedure. If the patient has colonized urine, use a percutaneous nephrostomy tube to maximally drain the kidney and continue antibiotics. The patient can then proceed with a staged percutaneous nephrolithotomy.
- Ensure that backup equipment is available. If using a lithotripter, a laser or electrohydraulic device should be available in the event that the lithotripter is inadequate. This will prevent intraoperative delays.

Prediction of complications remains challenging. Risk factors (Table 32.1) include anatomic abnormalities of the collecting system, indications for operation, and severe medical comorbidities. Several scoring systems have been used in this patient population in an attempt to standardize stone complexity classification to assist with prediction of complications, success of treatment, and the need for repeat procedures (Table 32.2). To date, no score has accurately predicted the risk of complications postoperatively, although many have been shown to accurately predict the stone-free rate postoperatively [5–7]. Interestingly, poor renal function preoperatively has been shown to predict the risk of worse postoperative outcomes [8].

Approximately 11% of urologists attempt to obtain percutaneous access to the kidney [9]. Many blame this low rate on lack of surgeon confidence. Interestingly, at high-volume centers, the rate of failure to obtain access to the kidney among interventional radiologists may be as high as 9%, while urologists enjoy a 2% risk of failed access, although urologic access may carry a higher risk of bleeding [10, 11]. Therefore, a command of the most common access-related complications and knowledge of how to both prevent and manage them would improve both operator confidence and patient care.

Complications in percutaneous nephrolithotomy (PCNL) often arise in selection of a calyx for puncture, particularly hemorrhage, or from injury to adjacent structures.

## Problems with initial puncture of the kidney

### Selection of calyx

When selecting a calyx for puncture, focus should be placed on obtaining access through a calyceal fornix rather than the calyceal infundibulum. This will minimize the risk of hemorrhage intraoperatively and postoperatively. Further, access should be attempted laterally as opposed to medially with respect to the kidney. The avoidance of medial access is necessary, as the renal artery and vein and renal pelvis are more easily injured when medial access is attempted. With the patient in the prone position, a retrograde pyelogram is performed. When inspecting the selected calyx to ensure that the puncture was obtained in the desired location, or if one wishes to delineate a posterior calyx, inject $CO_2$, not air, as the use of air increases the risk of air embolism in the event of inadvertent arteriovenous puncture. Care must be taken not to overfill the system, as this may cause extravasation, resulting in a poorly visualized collecting system. Should this occur, the surgeon might need to select a different calyx or merely wait until the contrast is absorbed. Following puncture of a calyx, confirmation of access should be checked by aspiration of contrast or by injection of saline to delineate the contrast. It is critical not to inject contrast material; otherwise, extravasation may occur.

**Table 32.1** Risk factors for complications of percutaneous nephrolithotomy.

| Factor | Example |
|---|---|
| Anatomic | Calyceal abnormalities<br>Malrotated/ectopic kidney<br>Horseshoe kidney |
| Surgical indications | Staghorn stones<br>Upper tract transitional cell carcinoma<br>Uteropelvic junction obstruction<br>Calyceal diverticulum |
| Medical comorbidities | Chronic obstructive pulmonary disease<br>Congestive heart failure/valvular heart disease<br>Morbid obesity<br>Kyphoscoliosis/limb contractures<br>Neurogenic bowel<br>Prior surgeries<br>Metabolic disorders (diabetes mellitus, cystinuria, renal tubular acidosis, sarcoid) |

### Hemorrhage

The overall rate of hemorrhage requiring blood transfusion during PCNL is estimated to be around 2–11% [12]. Most commonly, bleeding is secondary to injury of segmental arteries. Some important risk factors for

**Table 32.2** Scoring of stone complexity.

| Score | Parameters | Correlation with stone-free status and complications |
|---|---|---|
| S.T.O.N.E. Nephrolithometry score (Okhunov et al. [5]) | 1–4<br>Stone size<br>Tract length<br>Obstruction<br>Calyces involved<br>Essence (HU) | Stone-free status ($P = 0.001$)<br>Estimated blood loss ($P = 0.005$)<br>Operative time ($P = 0.001$)<br>Length of stay ($P = 0.001$) |
| Guy's stone score (Thomas et al. [6]) | 1–5<br>I – Solitary stone with simple anatomy<br>II – Solitary stone in upper pole or multiple stones in a patient with simple anatomy<br>III – Multiple stones in a kidney with abnormal anatomy, calyceal diverticulum, or partial staghorn calculus<br>IV – Staghorn calculus | Stone-free rate ($P = 0.01$) |
| CROES PCNL Nomogram (Smith et al. [7]) | Stone burden<br>Body mass index<br>Stone location<br>Stone count<br>Renal anomalies<br>Prior treatment<br>Multiple modalities<br>Case volume | Stone-free rate ($P < 0.01$)<br>If using the nomogram and predicted stone-free rate is 60%, perform PCNL or staged PCNL or use adjunct therapy |

PCNL, percutaneous nephrolithotomy.

intraoperative hemorrhage during PCNL include diabetes mellitus leading to arteriosclerosis, hypertension, stone size greater than 1250 mm$^2$, number of accesses, presence of staghorn calculi, and operative time greater than 58 minutes [12–14].

In most cases, bleeding during PCNL access can be attributed to laceration of subsegmental veins, and use of the Amplatz sheath to apply occlusive pressure will control the bleeding. To avoid tearing the renal parenchyma, once percutaneous access is obtained, the surgeon should avoid excessive up and down movement of the needle. In addition, medial insertion of the needle, which can lead to injury to the renal artery or vein or interlobar vessels, can incur further risk of bleeding.

If bleeding is excessive and the Amplatz sheath does not suffice, a large-caliber nephrostomy tube can be inserted or capped [15]. If that fails, insertion of a Kaye tamponade balloon catheter (Cook Medical, Bloomington, IN, USA) involves insertion of a 36 Fr occlusive balloon over a 5 Fr ureteral stent. This approach allows for drainage of the renal pelvis while tamponading the nephrostomy tract [16]. Once again, if this fails, the patient should be sent to interventional radiology for angiography. In cases in which conservative measures are unsuccessful, the use of super-selective angioembolization will help control the bleeding. Avoidance of perforation of the renal pelvis, which may occur in 7.2% of cases, is also critical [17].

## Guidewire insertion

Appropriate guidewire insertion is crucial to the success of the procedure. Kinking occurs when the tract from the skin to the kidney is not in a straight line. This is commonly related to timing of puncture: while initial puncture occurring during inspiration may lead to caudal displacement of the kidney, tract dilation occurring during expiration will lead to cranial displacement of the kidney, changing the tract trajectory and leading to guidewire kinking. Alternatively, guidewire kinking may result from an angled puncture.

It is essential to monitor the dilation of the tract fluoroscopically to ensure smooth passage over the wire, otherwise kinking of the guidewire is inevitable. When kinking of the guidewire is noted upon introduction, the surgeon should attempt to reposition the wire prior to re-attempting puncture. Never attempt nephrostomy tract dilation over a kinked guidewire, as this will likely lead to dilation tangential to the desired tract and increases the risk of injury to adjacent organs (Figure 32.1). Initially, the guidewire can be pulled back so that the kink is outside the nephrostomy tract. This is only possible if there is sufficient guidewire within the kidney to the ureter. The kink is subsequently straightened and an 8 Fr dilator is inserted over the guidewire to allow for subsequent tract dilation. Another option is to advance a 6 Fr dilator over the wire through the nephrostomy tract. The 6 Fr dilator is more flexible and can often be advanced over a moderate kink. The existing wire can be removed and exchanged for a new, unkinked super-stiff wire, which will allow for tract dilation. If all of the above techniques fail, removal of the guidewire and repeat puncture should be attempted.

## Arterial puncture

Cases of arterial puncture are confirmed with pulsatile bleeding noted from the lumen of the needle; this occurs with a medial puncture or if the needle is advanced too far medially. This can be checked in the 90° position under fluoroscopic guidance (Figure 32.2). A puncture of a vessel by an 18 Fr needle seldom poses a problem. One should merely withdraw the needle and attempt to insert it into the appropriate calyx. In the case illustrated, the surgeon merely had to withdraw the needle approximately 1 cm (Figure 32.2).

## Venous puncture

Occasionally, introduction of the guidewire leads to insertion into the renal vein. This is not all that uncommon. Fluoroscopic advancement of the wire will show the wire advancing into the inferior vena cava (Figure 32.3). Once again, withdrawal of the needle and repositioning is all that is required. If dilation over the wire into the tract is attempted, the renal vein is accessed and can appear to look like the renal pelvis without the calyces in the expected anatomic position. When this

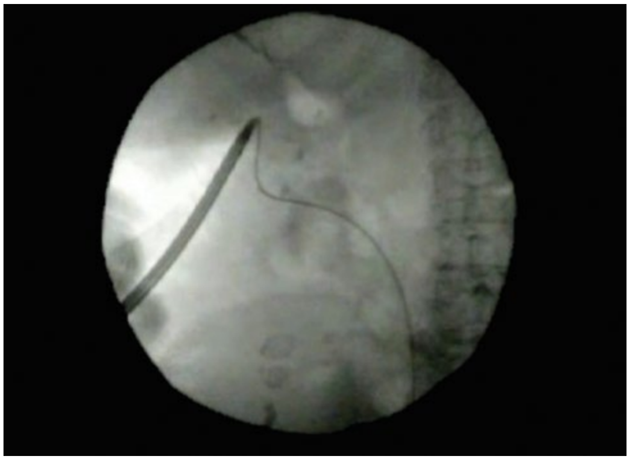

**Figure 32.1** Kinking of the guidewire at the time of obtaining percutaneous access. In this case, the wire was successfully repositioned with the assistance of an 8 Fr open-ended catheter and dilation proceeded without complication.

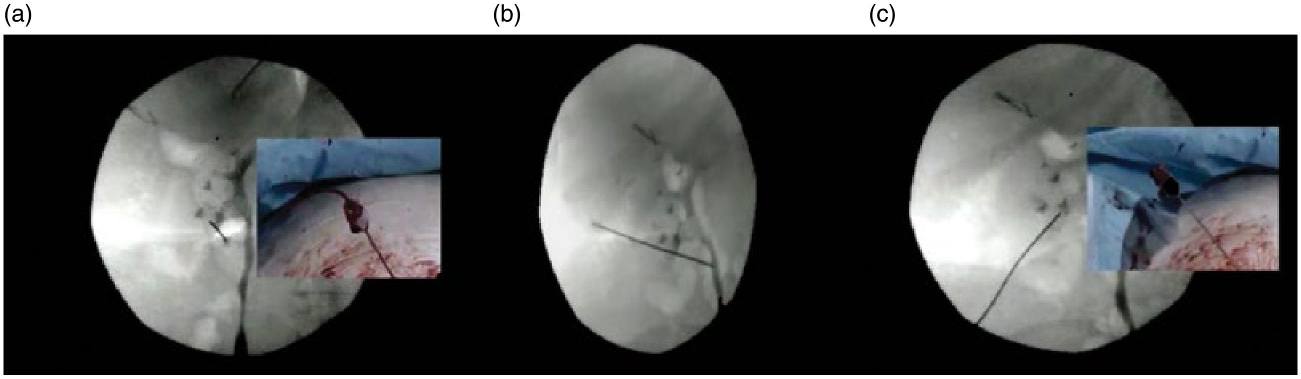

Figure 32.2 An example of inadvertent arterial puncture during attempted percutaneous access. (a) Needle is likely inserted into an interpolar artery. (b) The needle is then de-advanced with (c) cessation of hemorrhage.

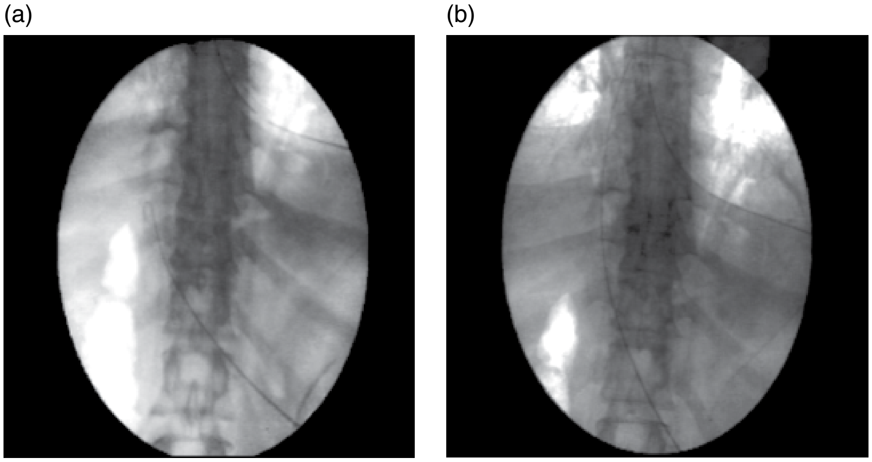
Figure 32.3 Inadvertent inferior vena cava (IVC) access at the time of left-sided percutaneous nephrolithotomy. (a) The wire is seen to be crossing the midline, and then (b) entering the IVC.



occurs, remove the nephroscope, gain access to the collecting system, dilate the tract, and insert a Councill catheter, with the balloon of the Councill catheter occluding the laceration in the renal vein. The balloon can be deflated after 48–72 hours.

### Issues encountered with a full staghorn calculus

The patient with a full staghorn calculus remains a persistent challenge at the time of needle placement. If the stone fully occludes the calyx, the needle will meet resistance at the level of the stone. When the needle is removed, the trocar portion of the needle may not be in the calyx and the guidewire cannot be advanced. To counteract this, the trocar (or the sheath of the needle) may be advanced onto the stone and the needle withdrawn. Another alternative is to dilate the tract up to the calyx and then displace the tissue overlying the stone with a grasping forceps. The Amplatz working sheath is then gently rotated until its edges are within the collecting system, and subsequently against the stone itself. Another option is to employ the technique originally described by Clayman et al. [18]. In this technique, ureteroscopic lithotripsy and stone extraction is performed to create space within the renal pelvis and create an appropriate calyx and an unobstructed route to the calyx to facilitate passage of the wire and subsequent percutaneous access.

## Injury to adjacent structures

### Nervous injury

The intercostal nerve and artery are at high risk for injury when supracostal access is attempted [19]. For this reason, supracostal access has been reported to have an increased risk of pain and bleeding. Attempting to access the kidney lateral to the paraspinous muscles within the lower half of the 11th intercostal space may minimize this risk. Occasionally, a bulge in the skin overlying the area of percutaneous access is seen and this is associated with nervous injury. Usually, the bulge resolves over time, and it is due to neuropraxia, but it may persist if indeed there was severe trauma to the nerve.

## Intrathoracic injury

Pleural or pulmonary injury is the most common complication encountered after hemorrhage in percutaneous renal surgery. It remains a rare complication, with incidences estimated to be approximately 0–12% [19–25]. The rate of injury increases threefold with supracostal access [26]. Lower rates of hydropneumothoraces were noted with a subcostal approach. The overall rate of pneumothorax was 1.5%, hydrothorax 0.5%, and hemothorax in 1% of patients. Only 0.5% of patients ultimately required intervention with tube thoracostomy. The risk of these complications increased with supracostal access into the upper pole calyces, which remains the most favorable approach for cases with staghorn calculi, upper pole calculi, or calyceal diverticuli of the upper pole.

When supracostal puncture is performed, it is essential to screen the diaphragm at the end of the surgery. If a pneumothorax or hydrothorax is present, it can be addressed while the patient is anesthetized. In most reports, complications have been managed conservatively or, if necessary, with a chest tube for drainage. Furthermore, in cases in which intraoperative hydropneumothorax is identified, this may be aspirated or drained using a pigtail catheter. In rare cases, thoracoscopy or an intraoperative thoracotomy may be required for patients with loculated effusion, empyema, or pleural effusion not responding to chest tube drainage.

## Injury to liver/spleen

Liver injuries typically occur as a complication of attempting access above the 11th rib. These injuries can be managed with observation alone. Patients should have serial abdominal exams and hematocrit measurements [27]. A follow-up CT scan can be obtained if concerns arise regarding the need for emergent surgical exploration.

Splenic injuries differ from liver injuries, as these injuries will require emergent open surgical exploration due to the significant bleeding often encountered [28]. If attempts to repair the spleen are unsuccessful, splenectomy should be the next step and serves as definitive management of the bleed. There have been several cases of splenic injury, which have been treated conservatively. If the patient is stable, then remove the tube after 72 hours while the patient is in the hospital. The patient should be observed closely for 6–8 hours in the event that urgent surgery is required.

Even less common are the reports of needles inserted at the time of percutaneous access, leading to an injury to the fundus of the gallbladder. In one case, the patient required a laparoscopic cholecystectomy due to biliary peritonitis.

## Injury to bowel

The rate of injury to the colon is reported to be as low as 0.06–0.2% overall [4, 29, 30]. Risk factors for colonic injury include retrorenal colon, renal anomalies (e.g. horseshoe kidney), any history of small bowel resection and diversion, or neurogenic bowel. Most injuries that occur result from lower calyceal punctures [31]. In patients with the aforementioned risk factors, a preoperative CT or laparoscopically guided access should be considered.

When a colonic injury is identified in a patient who does not have symptoms of peritonitis, patients may be managed conservative with placement of a double-J stent to address the ureter and insertion of a nephrostomy tube into the colonic lumen (Figure 32.4). This separation of the urinary and gastrointestinal tract should remove any opportunity for fistula formation. Broad-spectrum antibiotics should be given for 7–10 days with a follow-up nephrostogram to confirm closure of the fistulous tract. Peritonitis mandates abdominal exploration, creation of a diverting colostomy, and placement of an abdominal drain, in addition to closure of the perforation.

Injury to the duodenum is exceedingly rare, and is typically seen when the guidewire used to obtain access to the kidney has perforated through the renal pelvic hilum,

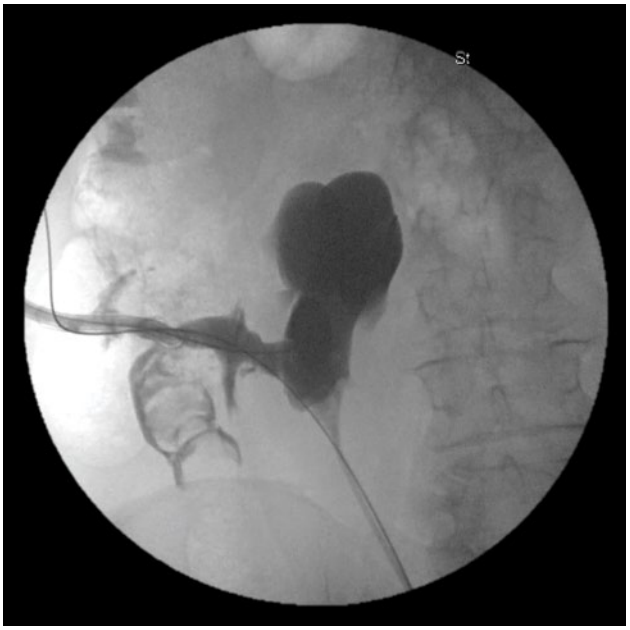


**Figure 32.4** An example of colonic injury at the time of percutaneous access. In this case, a nephrostomy tube was placed in the colonic lumen and a ureteral stent was placed in the ureter for maximal separation. The patient was treated with perioperative antibiotics for 7–10 days and recovered without difficulty.

and thereby penetrates the duodenum. If the injury is small, it can be managed by nasogastric decompression and a nephrostomy catheter. Nutritional status should be maintained by total parenteral nutrition.

## Conclusions

Appropriate technique at the time of obtaining percutaneous access for PCNL is crucial to avoid intraoperative complications. Selection of the appropriate calyx, immediate tamponade of intraoperative hemorrhage, avoidance of guidewire kinking, and careful maneuvering around staghorn calculi are important principles that decrease the risk of hemorrhage and unintentional injury to adjacent organs. Prevention of hemorrhage and organ injury during PCNL is dependent upon excellent technique at the time of creation of the nephrostomy tract. The surgeon can avoid most major complications by ensuring that the needle puncture is attempted postero-laterally, where possible, and that the guidewire is advanced down the ureter without kinking prior to dilation and placement of the Amplatz sheath. In the event of intraoperative hemorrhage or inadvertent injury to adjacent organs, the surgeon must have a command of the necessary techniques to quickly assess and address the problem to ensure an excellent postoperative outcome.

## Introduction

Prior to the advent and widespread adoption of endourologic techniques beginning in the early 1980s, the mainstay of surgical treatment for urolithiasis was open surgery. The risk of bleeding in the era of open renal stone surgery posed particular challenges for perioperative management. For example, in an evaluation of patients undergoing anatrophic nephrolithotomy over a period of 14.5 years, Assimos et al. reported a 6.4% rate of significant postoperative bleeding [1]. A more recent analysis by Al-Kohlany et al., evaluating complications of open renal stone surgery, demonstrated a 24.5% rate of intraoperative hemorrhage requiring transfusion and an 8.9% rate of massive hematuria requiring transfusion [2].

In the modern era, minimally invasive treatments for urolithiasis, such as shock-wave lithotripsy, ureteroscopy, percutaneous nephrolithotomy (PCNL), and laparoscopy, have all but replaced open surgery for large kidney stones in centers with access to such technology and expertise. PCNL, in particular, has had a considerable impact on improving hospital lengths of stay, recovery times, and overall morbidity [3]. However, despite these advances, hemorrhagic complications remain a potent concern during and after PCNL [4–6]. The PCNL Global Study by the Clinical Research Office of the Endourologial Society, which prospectively collected data on consecutive PCNLs performed by centers across the world over a one-year period, found a 7.8% rate of significant bleeding and a blood transfusion rate of 5.7% [4]. Contemporary ranges of bleeding during and after PCNL requiring transfusion are reported to be between 1% and 11% [5–7]. Proper management of perioperative bleeding plays an important role in the safe and effective treatment of kidney stones with PCNL, and the management of such bleeding should be familiar to those performing PCNL as well as those involved in the care of these patients.

The objective of this chapter is to review the various hemorrhagic complications encountered during and after PCNL, the management of these complications, and strategies to reduce their occurrence. This chapter will also discuss perioperative risk stratification and patient optimization, as well as technical considerations during PCNL which influence hemorrhagic complications. It is through the combination of optimizing patient risk factors pre- and perioperatively, executing excellent surgical technique, recognizing bleeding early, and managing bleeding rapidly that hemorrhagic complications during and after PCNL can be minimized and their consequences mitigated.

## Etiology of hemorrhage from percutaneous nephrolithotomy

Bleeding during and after PCNL can occur at any step throughout the procedure, including needle puncture, dilation of the percutaneous tract, excessive torqueing of the renal parenchyma through an established access sheath, aggressive stone manipulation and extraction, from collateral damage to adjacent organs and blood vessels, during nephrostomy tube removal, and in the immediate or delayed postoperative period [8]. Hemorrhage results from either damage to the kidney parenchyma, disruption of the peri- or intrarenal vessels, or injury to adjacent structures.

Renal parenchymal bleeding, believed to stem most commonly from the interlobular vessels, is often mild, apparent during surgery, and frequently can be

controlled with intraoperative tamponade from the access sheath, and with larger bore nephrostomy or nephroureteral catheters postoperatively. Injury to the larger renal vessels, such as the arcuate, interlobar, lobar, and segmental vessels, is thought to cause more significant bleeding that may limit vision during PCNL and can cause continued significant blood loss postoperatively as well. For vessels in spasm, bleeding may be minor during surgery, but once the spasm abates, bleeding and its effects often become apparent within the first 24–48 hours postoperatively.

Injury to these larger vessels is also believed to be the cause of delayed bleeding. Such delayed bleeding often takes one of two forms: arteriovenous fistulas and pseudoaneurysms. Arteriovenous fistulas arise when a lacerated artery and vein in proximity to each other form a direct connection while healing. Pseudoaneurysms result when surgery injures the wall of a high-pressure artery and blood then leaks into a lower pressure area such as the collecting system, connective tissue, or vein [9]. In both of these cases, significant renal bleeding can present in the early postoperative course or in delayed fashion as late as a number of weeks postoperatively.

## Risk factors associated with hemorrhage during percutaneous nephrolithotomy

Myriad factors have been linked to PCNL-related hemorrhage, and can be grouped together as patient-related factors, operative-related factors, and stone-related factors.

### Patient-related factors

Patient-related factors that have been correlated with increased bleeding risk are numerous and those most consistently shown to increase perioperative bleeding on multivariate analysis include obesity, certain comorbidities such as hypertension, arteriosclerosis and diabetes, older age, patient frailty, higher American Society of Anesthesiology (ASA) classification, renal insufficiency, lack of preoperative hydronephrosis, history of prior renal surgery, renal anomalies, underlying or prior urinary tract infections, and the use of anticoagulants [10–12]. One group has evaluated the effect of prior renal surgery on hemorrhage and has found prior open stone surgery was significantly more likely to be associated with post-PCNL hemorrhage compared to prior PCNL or shock-wave lithotripsy [13]. Interestingly, this contrasts with findings from another group in the same geographic region who found no differences in patients previously treated with shock-wave lithotripsy or open stone surgery [14].

Recent or recurrent urinary tract infections can lead to chronically inflamed tissue, which tends to bleed more easily. Additionally, infection is known to impair effective blood clotting. Furthermore, patient frailty, as measured by Charlson comorbidity index (CCI) and activities of daily living, has been linked to overall patient complications and may be related to increased bleeding risk [15, 16].

### Operative-related factors

Operative and technical factors that have been shown to influence and increase bleeding risk include longer operative duration, larger access tract size, less surgeon experience, use of multiple access tracts, upper pole calyceal access, longer intraoperative time to successful renal puncture and larger bore nephroscopes [10, 17–23]. Compared with smaller access sheaths (≤18 Fr), larger access sheath size was associated with increased hemorrhage risk (threefold increased risk for access sheaths 24–26 Fr and almost fivefold increased risk for access sheaths 27–30 Fr) [24]. Increasing number of access tracts, in particular three or more, routinely appears to correlate with increased risk for higher blood loss and transfusions following PCNL [17, 20–22, 25].

Increasing operative time has also been shown to increase bleeding risk. Though most likely a continuum, surgical duration in excess of approximately 110–120 minutes has been predictive of post-PCNL bleeding [26, 27]. At least one study has suggested that less surgeon experience was associated with an almost threefold elevated hemorrhage risk (0.6% for an experienced endourologist compared to 1.7% for a general urologist or trainee) [18].

A few studies have evaluated the relationship between PCNL-related hemorrhage and hospital case volume, and the evidence remains equivocal as to how hospital PCNL volume influences bleeding risk. One study from the United States used the Nationwide Inpatient Sample and found transfusion rates were highest in the lowest and highest quartile volume centers on univariate analysis, however hospital PCNL case volume was not found to independently predict for transfusions on multivariate analysis [28]. In another study from the United Kingdom, no difference in major hemorrhage events was seen among those hospitals performing low (<10 PCNLs per year; 1.3%), medium (10–20 PCNLs per year; 1.5%), and high (>20 PCNLs per year; 1.5%) volumes of PCNLs [29]. Results from the Global PCNL Global study did show a higher reported rate of bleeding (9% vs. 5.5%), mean hemoglobin change (3.9 vs. 3.5 mg/dl), and blood transfusion rate (5.2% vs. 3.4%) in low volume (<77 PCNLs per year) compared to high-volume (>77 PCNLs per year) centers [30].

Several studies have shown that renal access obtained by a urologist is associated with less bleeding, fewer complications, and a higher stone-free rate than renal access obtained by a radiologist [31–33]. This is thought to be related to the fact that the goals of the radiologist and urologist may differ in these circumstances. The typical tract created by the urologist is often a more direct route, and often more superiorly located (Figure 33.1). It is prudent to assess the radiologist-obtained renal access tract prior to tract dilation, and this can be done with multiplanar fluoroscopy and antegrade nephrostography. If suboptimal access is found, there should be a low threshold for obtaining a new, better access.

### Stone-related factors

Lastly, stone composition and burden have been correlated with increased bleeding risks. In particular, staghorn stone configuration appears to be consistently related to increased risk of perioperative PCNL bleeding. In at least one report, an almost 30% increased risk of bleeding was encountered when more than two access tracts were used to approach staghorn calculi [21].

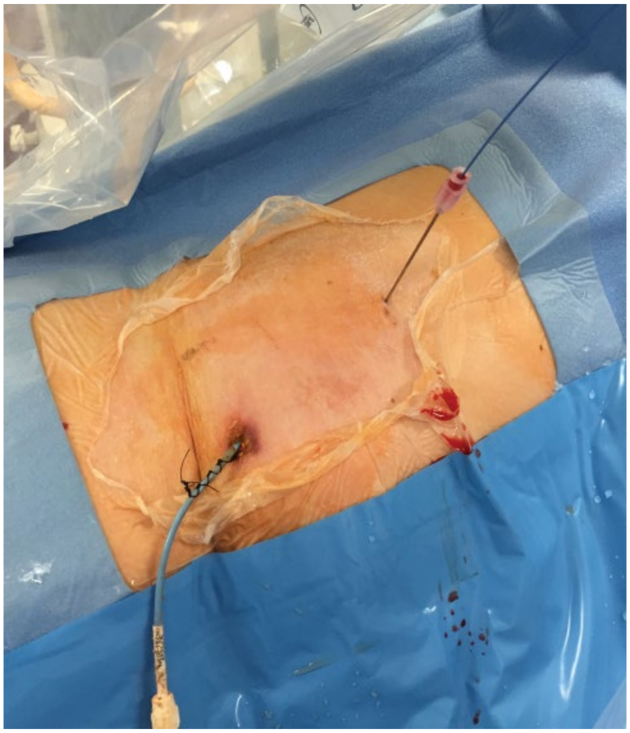

**Figure 33.1** Percutaneous access obtained by interventional radiologist (left side of image) versus percutaneous access obtained by endourologist (right side of image). The endourologist access tract is superiorly located and provides a direct route to renal calculus.

## Preoperative patient assessment and optimization

Absolute contraindications to PCNL include uncorrected coagulopathy and active infection. A complete history and physical examination is important in all patients prior to PCNL, and close attention should be paid to personal and family history of blood dyscrasias and coagulopathic states (clotting factor deficiencies, idiopathic thrombocytopenic purpura, coronary artery stenting, mechanical heart valves, atrial fibrillation, venous thromboembolism, etc.). Medications should be reviewed with the patient with a particular eye towards antithrombotic medications and herbal supplements. Full laboratory evaluation, including complete blood count, serum electrolytes, creatinine level, and coagulation parameters, are important to determine preoperatively. Appropriately screened and cross-matched blood products should be available.

Previous renal and retroperitoneal surgery should be specifically elicited, as previous open renal stone surgery may increase the risk of angioembolization, while prior PCNL may not [34]. Preoperative cross-sectional imaging is recommended to help fully understand renal stone burden and anatomy, and to evaluate for anatomical abnormalities and perinephric organ location. Preoperative negative urine cultures should be the goal, and review of prior positive urine cultures and sensitivities are important in patients with a history of urinary tract infections, as these can influence perioperative antibiotic choices.

Scrutiny of any antiplatelet and anticoagulant medications is paramount as the widespread use of these agents becomes more frequent and the number of agents utilized continues to grow. Determining the indications for such antithrombotics is imperative and can have ramifications on the perioperative management of such medications, including the relative risks of continuing versus stopping them, and whether bridging regimens are indicated. Further details on this topic can be found in Chapter 5.

In the operating room, immediately preceding PCNL, maintaining adequate patient temperature is imperative as efficient clot formation depends on body temperature, and lower core body temperatures are associated with inefficient clot formation [35, 36]. To this end, temperature monitoring in the perioperative period is important, and increasing ambient room temperature and utilizing convective air-warming systems can combat rapid body temperature losses associated with clothes removal and anesthetic induction prior to the start of surgery. During patient positioning alone, core body temperatures can fall by approximately 1°C [36, 37]. Furthermore, it is important to use warmed irrigation fluid when available.

## Intraoperative hemorrhage: recognition and management strategies

Intraoperative hemorrhage is typically not subtle, and can happen at any step during PCNL, from initial percutaneous access to final urinary drainage. It is thought that the moments of greatest hazard are: (i) during initial access and percutaneous tract dilation, when any of the perinephric organs or vascular structures is at risk for nonvisualized (blind) puncture injury, and (ii) during excessive torqueing of the sheath or nephroscope during the procedure, which can result in renal parenchymal shearing and tearing.

The first step to minimizing bleeding begins with the initial renal puncture. The preferred approach involves an "end-on" calyceal puncture, where the access needle passes centrally through the longitudinal axis of the targeted posterior calyx. Moreover, the preferred access should traverse Brödel's avascular plane along the shortest and straightest track from the skin to the collecting system, thereby minimizing the amount of renal parenchymal disruption. Excessive medial advancement of renal dilators should be avoided and careful note should be made to pass or situate dilators just to the forniceal–calyx junction. Creating as straight and short a percutaneous track as possible is advised, as is dilating in as straight a manner as possible between skin and target calyx; this will reduce the possibility of guidewire kinking which can hinder the passage of subsequent catheters, dilators, and sheaths. These strategies are thought to reduce the risk of injury to the interlobar, segmental, and main renal vessels, and to reduce the risk of renal pelvis perforation [36, 38–42]. Routine use of flexible nephroscopes, when available, can help reduce overly aggressive torqueing of the nephroscope and access sheath, which can lead to renal parenchymal tearing and resulting increased bleeding [43].

When significant bleeding is encountered, especially during percutaneous access and tract dilation, the anesthesia team should be notified immediately so that preparations can be made for closer hemodynamic monitoring and possible transfusion of blood products. Bleeding in these instances is frequently self-limited, and can usually be managed with tamponade from the access sheath once it is properly positioned across the renal parenchyma. In most cases, PCNL can then proceed as planned.

During stone manipulation, the access sheath should remain positioned across the renal parenchyma to avoid repeated shearing and loss of tamponade, both of which will increased bleeding and obscure vision. Removing stones or fragments too large for the access sheath can lead to sharp and everted deformation of the working sheath, which can lead to tract tearing and increased bleeding upon sheath removal. Severe bleeding has been reported following rupture of a renal working sheath [44]. To prevent these issues from arising, excessive force should be minimized when removing calculi, and attempted removal of stones that are too large should be avoided.

If significant bleeding or the passage of blood clots persists through the sheath, visualization may be impaired. When visualization is too poor to continue safely, it is best to place a large-bore nephrostomy tube and return at a later date, after bleeding has ceased. Bleeding severe enough to cause early termination of PCNL is infrequent, reported in about 0.2% of cases [45, 46].

Hemodynamic instability, often evidenced by tachycardia, hypotension, and potentially increasing vasopressor requirement from the anesthesia team, are concerning and should alert the surgeon to the possibility of large blood loss. Good communication with the anesthesia team is critical in these instances.

It should be noted that intraoperative assessment of blood counts (hemoglobin, hematocrit) may underestimate the degree of blood loss in the acute setting and initiating blood product transfusions should be considered when signs of hemorrhagic shock exist despite a higher than expected blood count intraoperatively. Similarly, a steady but still significant blood loss may be underperceived due to irrigation fluids, and this can often manifest itself as gradually worsening hypotension and tachycardia as the PCNL proceeds. This is most common during longer PCNLs, and is one of the reasons certain stone centers terminate PCNLs after a set duration of time (often 2–3 hours), and stage the procedure thereafter if more work is still necessary.

When heavy bleeding is encountered, vision can be improved by moving the access sheath closer to the stone or collecting system wall. Irrigation pressure can also be increased, but this should be done with caution as it can lead to increased pyelosinus, pyelovenous, and pyelolymphatic fluid absorption and may increase the risk for infection and sepsis. If vision remains limited or bleeding persists, a large-diameter catheter (e.g. Councill tip) can be placed over a wire and through the sheath into the kidney. The catheter balloon can be inflated (approximately 3–5 ml) to provide additional compression in the renal parenchyma to supplement the sheath's tamponade on the tract. After approximately 5 minutes, the balloon can be deflated and the bleeding reassessed. If the bleeding persists, the catheter can be advanced or withdrawn slightly within the renal parenchyma and the balloon reinflated with a view to achieving hemostasis. At this point, the procedure can be terminated if it is felt that the risk of further bleeding outweighs the benefits of continuing. The sheath can be removed and the catheter can be left in place for urinary drainage and to facilitate subsequent renal access. Another option is to use a large-bore nephroureteral catheter or re-entry tube to provide tract tamponade and maintain access to the collecting system and ureter.

A Kaye tamponade balloon catheter (Cook Medical, Bloomington, IN, USA) can be advanced over a wire into the renal pelvis under fluoroscopic guidance and provides excellent control of tract bleeding while maintaining collecting system access [47, 48]. This catheter provides balloon tamponade along the entire length of the tract and retains entry and access to the pelvicalyceal system. In the absence of a Kaye or other suitable catheter, the balloon dilator used for initial tract dilation and access sheath placement can be repositioned and inflated along the length of the access tract.

These techniques allow for compression along the entire length of the access tract. Moreover, they usually provide adequate tamponade of less common sources of bleeding such as subcostal or intercostal vessels and bleeding stemming from unintended organ injury during initial renal puncture and dilation (e.g. spleen, liver). Such infrequent sources of PCNL-related hemorrhage usually manifest at the conclusion of surgery, just after removal of the access sheath, or at the time of nephrostomy tube removal.

Refractory bleeding, significant blood clots emanating from the nephrostomy catheter, or hemodynamic instability after any of the above maneuvers suggests ongoing, often arterial, bleeding (Figure 33.2). Attention should be paid to the patient's vital signs, and if there is concern for impending hemorrhagic shock, blood product transfusions should be initiated, the procedure should be aborted, and a low threshold should exist to transfer patients directly from the operative suite to angiography for possible angioembolization. In the absence of hard signs of hemorrhagic shock, the patient may be monitored with frequent vital signs assessments and serial assessment of blood counts. In instances where bleeding is believed to be from an intercostal vessel, a small incision and cutdown directly onto the caudal aspect of the involved rib, allowing for vascular control, may be considered [36].

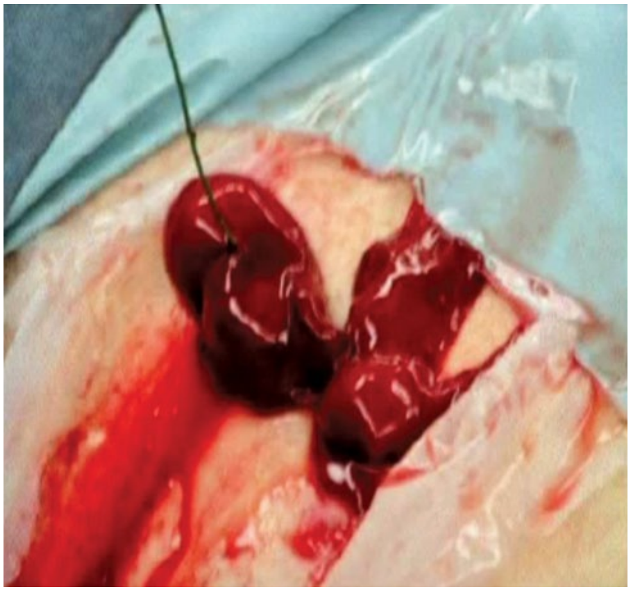

**Figure 33.2** Significant blood clots emanating from the nephrostomy tract suggests ongoing, often arterial, bleeding.

Catastrophic bleeding in the setting of severe hemodynamic instability may preclude safe transit for angioembolization. This can result from injury to the main renal vessels and usually occurs during overly forceful tract dilation or too medial placement of initial puncture needle and tract. Very occasionally, though, this may result from overly aggressive nephroscope and renal manipulation. Thankfully, main renal vessel injury is rare (0.4%) [45, 49].

Strategies to avoid this complication include ensuring urine return through the puncture needle prior to tract dilation, withdrawing the needle and choosing a different puncture if blood is aspirated during initial needle puncture, and directing a stiff guidewire down the ureter prior to tract dilation or heavy stone manipulation to direct dilation forces down the ureter and away from the renal hilum. These instances of life-threatening hemorrhage appear rare in contemporary PCNL series. When this is encountered and the patient cannot be safely transferred for angioembolization or this resource is not available, then retroperitoneal renal exploration can be attempted to achieve vascular control; however, this often results in nephrectomy.

## Alternatives and adjuncts to tract tamponade

Modifications to conventional catheter tamponade for tract bleeding have been proposed, and include a variety of hemostatic inducing agents, an antifibrinolytic (tranexamic acid), electrocautery, and cryoablation. Fibrin glue, porcine-derived absorbable gelatin compressed sponges (Gelfoam, Pfizer, Inc., New York, NY, USA), oxidized cellulose (Surgicel, Ethicon, Somerville, NJ, USA), fibrin-soaked porcine gelatin sponges (Spongostan, Ferrosan Medical Devices, Copenhagen, Denmark), sterile equine collagen matrix coated with human thrombin, fibrinogen, and fibrin glue (TachoSil, Nycomed, Zurich, Switzerland), and bovine collagen granules (FloSeal, Baxter Medical, Deerfield, IL, USA) have been used in an attempt to reduce post-PCNL bleeding events. Descriptions exist of using these agents alone or in combination with various catheters to help target delivery of the hemostatic agent to only the percutaneous renal tract.

One of the more elaborate methods includes a hemostatic "sandwich" consisting of gelatin matrix hemostatic sealant interposed between two Councill tip nephrostomy tubes, each with inflated balloons [50–55]. For uncomplicated PCNL without refractory bleeding, Abbott et al. proposed the use of a hemostatic sealant as an adjunct to "tubeless" PCNL [56], whereby the nephrostomy tract is occluded by thrombin-soaked absorptive gelatin (Gelfoam) and the skin closed without a percutaneous drainage catheter. A similar technique was earlier described by Kaufmann et al. [57], who used FloSeal to similar effect.

More recent meta-analyses evaluating the role of hemostatic agents provide no convincing evidence that the use of such agents along the access tract provides any significant benefit in terms of blood loss, transfusion requirement, complications, fevers, or analgesic requirement [58, 59]. Overall, it appears the use of hemostatic agents is safe, but comes at considerable cost and does not appear to meaningfully change the bleeding risk.

At least one randomized controlled prospective study with 200 patients has analyzed the effect of tranexamic acid, an antifibrinolytic, on bleeding following PCNL [60]. In this initial study, blood transfusion rate was significantly lower (2% vs. 11%; $P = 0.018$) and operative time was significantly less (48 minutes vs. 71 minutes; P 0.0001) in the group receiving tranexamic acid. Though encouraging, further studies are necessary to better understand the true advantages and disadvantages of this approach.

Cauterization of the percutaneous access tract has also been explored, primarily in an effort to achieve successful tubeless PCNL. A retrospective study found a statistically significant decrease in blood transfusion rate among patients who underwent electrocautery of the PCNL tract compared to those who did not [61]. However, the authors point out care must be taken to avoid inadvertent injury to other perinephric structures.

Okeke et al. proposed cryotherapy of the nephrostomy tract as another hemostatic alternative [62]. In this technique, a cryoprobe traverses the nephrostomy tract and a single 10-minute freeze–thaw cycle was applied (Figure 33.3). It was found that the cryotherapy group had significantly shorter hospital stays, decreased rates of delayed bleeding, and decreased urinary leak rates. However, use of the cryotherapy system was found to be cumbersome and led to longer operative times, thereby calling into question the potential benefit.

## Management of postoperative and delayed hemorrhage

In the postoperative period, patients should be monitored for changes in vital signs and for hematuria, both from the nephrostomy tube and per urethra. Bleeding

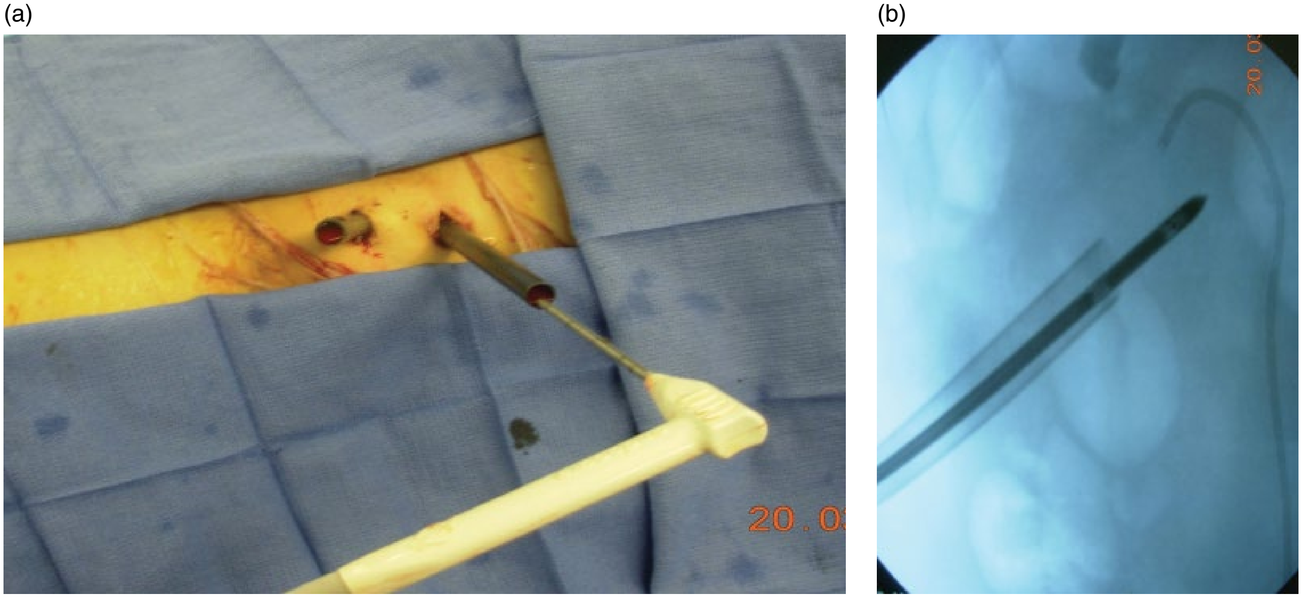

Figure 33.3 (a) Cryoprobe introduced through percutaneous nephrostomy access sheath. (b) Fluoroscopic image of cryoprobe within tract during freeze–thaw cycle.

originating from the parenchyma usually manifests as hematuria through the nephrostomy tube and or urethral catheter, while bleeding from the percutaneous tract can present as bleeding around the nephrostomy tube. Moderate hematuria can often be managed by clamping the nephrostomy tube temporarily or elevating the nephrotomy drainage bag above the level of the ipsilateral kidney, both of which aim to facilitate clot formation within the kidney and potentiate internal tamponade.

Heavy tract bleeding or hematuria in the immediate postoperative period can often be managed through a combination of local compression and nephrostomy tube clamping. Local compression becomes particularly important in instances where no nephrostomy tube is placed (i.e. in “tubeless” PCNL). This can be accomplished by repositioning the patient completely supine, which allows the overlying organs to provide anterior pressure, and placing a 3-liter fluid bag underneath the ipsilateral flank, which increases posterior compression (Figure 33.4). Alternatively, hands or fists situated over the ipsilateral abdomen and back can provide direct pressure.

Following the immediate postoperative period, persistent or worsening hematuria should raise suspicion for hemorrhage that may require intervention. The color of hematuric urine from the nephrostomy tube and urethral catheter provide some approximation of the degree of ongoing bleeding. When heavier hematuria or clot passage is noted, clamping the nephrostomy tube for a number of hours postoperatively is advised. When the nephrostomy tube is unclamped later, light pink to clear urine output suggests severe bleeding has abated.

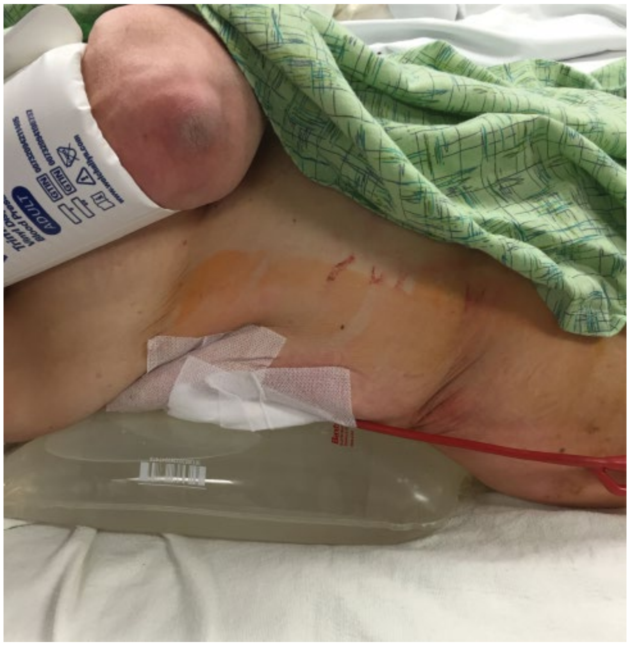

**Figure 33.4** Placing the patient supine with 3-liter fluid bag underneath the ipsilateral flank can assist with local compression for hemostasis.

Occasionally, heavy bleeding arises with nephrostomy catheter removal. This often stems from an open arterial branch that was occluded by the nephrostomy catheter or by a vessel that was in spasm but opens with catheter removal. Rapid catheter reinsertion and external tract compression are recommended in this scenario, with consideration for subsequent renal angiography and possible embolization, especially when accompanied by signs of hypovolemia and hemorrhagic shock [36, 45].

When the above-described measures are unsuccessful in controlling bleeding or when the severity and acuity of bleeding are more drastic, renal angiography with the option of selective or superselective embolization is recommended. In centers where the technique is available, it is often the preferred first-line procedure as it can be both diagnostic and therapeutic in the same setting (Figure 33.5). In general, indications for renal angioembolization include the need for repeated transfusions, ongoing hemoglobin decrease, hemodynamic instability, repeated bladder clot evacuations, and imaging (e.g. Doppler ultrasound or computed tomography) suggestive of vascular lesions [19, 45, 63]. Patients who continue to show significant hematuria, large blood clot passage per urethra or accumulation of clots within the bladder (Figure 33.6), ongoing hemoglobin loss with hypotension and tachycardia in the few days following PCNL, as well as those who return within a week to a month after hospital discharge with similar symptoms and signs should be routinely considered for renal angiography and possible embolization.

In these situations, the most common vascular lesions encountered are arterial pseudoaneurysms and arteriovenous fistulas, and less frequently arterial lacerations. Vascular wall injury during PCNL can lead to pseudoaneurysms in high-pressured vessels. Arteriovenous fistulas develop when high-pressured arteries form an inappropriate communication with and drain directly into the lower pressured veins. Arteries that heal with a direct communication to the collecting system may present as intermittent, severe hematuria, clot passage, and flank pain [5, 9]. Contemporary reviews show an approximately 1–1.5% incidence of renal angioembolization following PCNL, and increased experience with this technique has almost completely obviated the need for partial and total nephrectomy to control bleeding in centers with available angioembolization technology and expertise [5–8, 33, 64, 65]. The most common

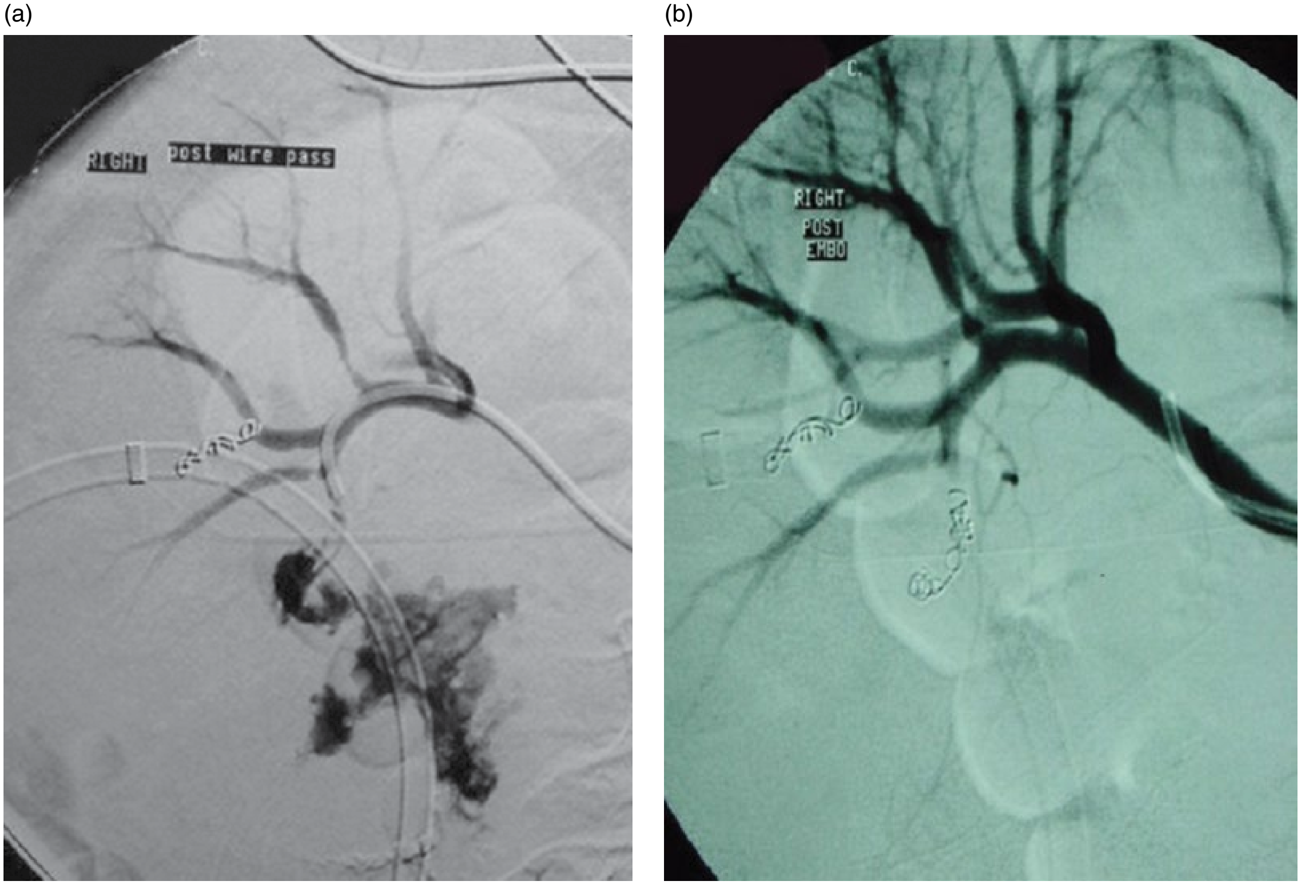

**Figure 33.5** (a) Angiography demonstrates vascular extravasation in arterial branches supplying kidney. (b) Post-coil angioembolization results in cessation of extravasation and control of bleeding.

site of vascular injury requiring angioembolization is variable and appears to coincide most with the preferred calyx of access rather than an obviously anatomically increased incidence with one location relative to another [18, 19, 66].

Bleeding associated with pseudoaneurysms and arteriovenous fistulas is often referred to as delayed bleeding, as the average onset of hemorrhage appears to be one to two weeks after surgery. However, delayed bleeding can present as much as a month or longer following PCNL [33, 35, 36]. Initial selective renal arterial embolization is successful at controlling renal bleeding 80–90% of the time [6, 66, 67]. In one series reviewing initial angioembolization failures, renal arterial embolization was found to initially fail in approximately 10% of cases (12 out of 117 patients), with successful hemorrhage control during second embolization in 8 out of 12 patients, during third embolization in 3 out of 12 patients, and a single patient went on to require nephrectomy [67].

When analyzing risk factors for failed initial angioembolization, multiple bleeding sites and multiple percutaneous tracts were found to correlate with angioembolization failure. In a 12-year review from a single institution, superselective angioembolization was found to have an initial success rate of 85% (35 out of 41 patients) and of those who failed, two patients went on to undergo nephrectomy for persistent bleeding [66]. In each case, multiple punctures (>3) were performed for a large-burden staghorn calculus. In other instances, failed angioembolization eventually leading to nephrectomy was associated with underlying, and previously unrecognized, malignancy (renal cell carcinoma or upper tract urothelial carcinoma), and a high index of suspicion should be maintained in cases of failed initial superselective angioembolization [6, 68].

Following superselective renal angioembolization, the vast majority of patients (up to 90%) can experience some combination of flank pain, nausea and vomiting, and leukocytosis, collectively referred to as postembolization syndrome [68, 69]. Pain can be severe following embolization of large swaths of renal parenchyma, and anti-inflammatories, and in some instances steroids, may be used prophylactically. Loss

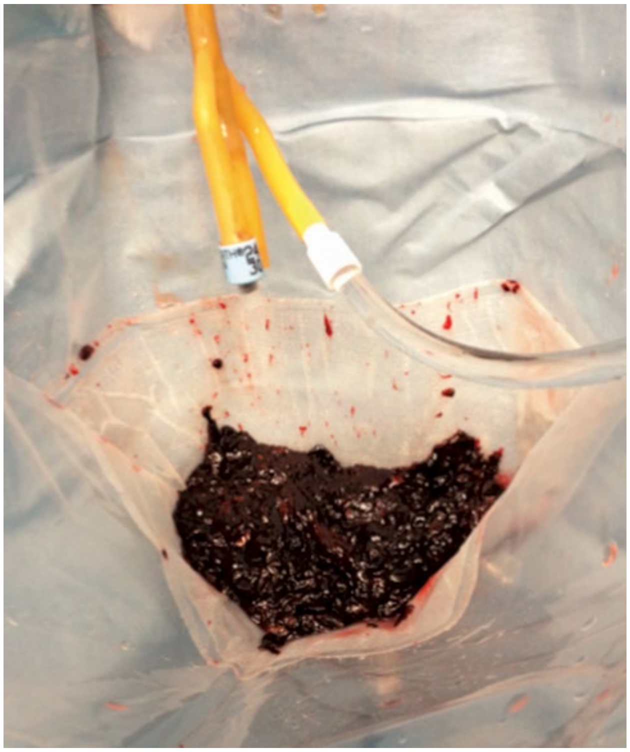

**Figure 33.6** Significant hematuria and clot burden from the bladder that persists after PCNL may indicate arterial bleeding that may require angioembolization.

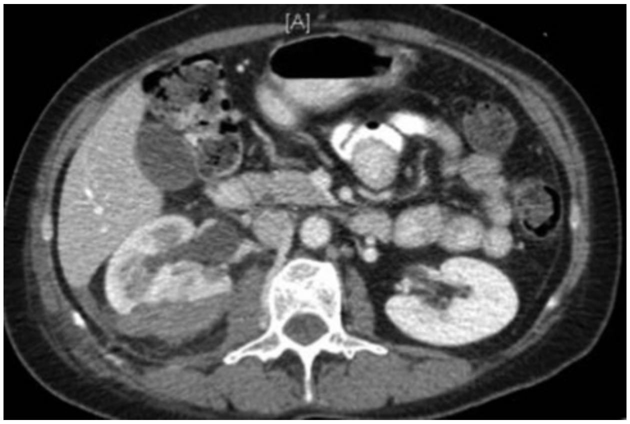

**Figure 33.7** Cross-sectional axial CT demonstrating right-sided perinephric hematoma, which can occur in up to one-third of patients undergoing PCNL.

of renal function following angioembolization has been evaluated, and it appears the effects are most pronounced in patients with solitary kidneys with one-third (3 out of 9 patients) showing increased serum creatinine but none requiring dialysis in one study. Interestingly, in the same study, 20% of patients (6 out of 30) showed no photopenic areas on renal scintigraphy, and renal function in these ipsilateral renal units was seen to significantly increase from 25% to 34% at mean follow-up of 3.9 years [70]. Coil migration, albeit rare following superselective renal angioembolization, has been described and is seen most commonly in the lung or urinary tract with resultant urinary tract obstruction [71, 72].

Rarely, lumbar artery injury can be the source of significant bleeding after PCNL, and angioembolization has been employed successfully to manage this complication as well, although this requires a limited aortogram and should be considered if the initial renal angiogram shows no bleeding [73, 74].

Perinephric and subcapsular hematomas may occur in up to one-third of PCNLs, and are usually clinically silent with fewer than 1% requiring intervention with selective angioembolization (Figure 33.7). Prior shock-wave lithotripsy predisposes to perinephric hematoma. Perinephric hematoma should be considered when post-PCNL hemoglobin continues to drop despite clear urine drainage. The use of triphasic CT in these situation can help make the diagnosis and help distinguish active renal bleeding from urinary leak and urinoma formation [75, 76]. In rare instances, a perinephric hematoma may lead to a "Page kidney," where incomplete or delayed resorption of the hematoma causes renal compression and relative hypoperfusion and the subsequent development of hypertension. In these instances, percutaneous drainage of the perinephric hematoma is suggested [63, 75].

## Conclusions

Hemorrhagic complications associated with PCNL remain common and are often associated with larger stone burdens, prolonged operative times, surgeon inexperience and multi-tract procedures. Most bleeding-related complications can be managed with conservative measures. Numerous techniques are available to address intraoperative and postoperative hemorrhage. For serious and life-threatening hemorrhage and for persistent bleeding refractory to conservative measures, superselective renal angioembolization has proven itself as an excellent technique to control post-PCNL bleeding with relatively minor associated morbidity. Early recognition and management of bleeding complications require attention to both technical and patient-related factors, and are critical to executing safe and effective percutaneous nephrolithotomy.

## Introduction

Percutaneous nephrolithotomy (PCNL) is the recommended treatment modality for renal stones greater than 20 mm in size, staghorn stones, infection-based stones, and a variety of other indications such as percutaneous renal tumor treatment, stones in kidneys with utereropelvic junction (UPJ) configuration, and for treating stones in patients with urinary diversions [1, 2]. The concept of percutaneous stone surgery was first described by Rupel and Brown in 1941. The authors inserted a cystoscope through a percutaneous nephrostomy tube track in order to treat a renal stone in a solitary kidney [3]. Fernström and Johannson later described the technique of using serial dilation to percutaneously treat a renal stone in 1976 [4]. Since these early descriptions, experience and techniques have expanded and now PCNL is widely performed worldwide. The percutaneous approach means there is a certain risk of injury to structures surrounding the kidney. Therefore, successful utilization of this approach relies on methods to minimize complications and maximize the ability to treat the pathology. Percutaneous access to the kidney is obtained for a number of other indications aside from stone management, such as antegrade management of UPJ obstruction, antegrade management of upper tract urothelial cancer, and percutaneous ablation of renal masses.

There are many possible complications with this approach, yet the proximity of the kidneys to the diaphragm and pleura make thoracic complications a unique and important complication to consider. This chapter discusses the type of thoracic complications that are possible as a result of percutaneous renal surgery. We also review the relevant literature regarding the incidence and management of thoracic complications so that the reader gains an updated management algorithm.

## Anatomic considerations

The kidneys are located in the superior aspect of the retroperitoneum, in close proximity to the diaphragm and pleura. The superior pole of the right kidney is typically located slightly superior to the 12th rib, while the superior aspect of the left kidney is often located just beneath the 11th rib [5]. The intercostal spaces are located between the ribs and are named for the rib superior to the space. Therefore, the 11th intercostal space is located between the 11th and 12th ribs. Figure 34.1 demonstrates the anatomic relationships between the kidneys, ribs, and parietal pleura.

The lungs are enveloped by two layers of a thin, serous, membrane called the pleura. The parietal pleura lines the internal aspect of the thoracic cavity while the visceral pleura directly surrounds each lung. These two layers of pleura are generally in close proximity with only a small amount of pleural fluid between them that serves as a lubricant, allowing the two layers to slide past each other with minimal friction. The potential space between these two layers is called the pleural space. Thoracic complications arise when significant air or fluid fills the pleural space, causing irritation or compression of the lungs [6].

Posteriorly, in the midscapular line, the parietal pleura attaches to the internal aspect of the 12th rib [7]. At the midaxillary line, the pleural is approximately at the level of the 10th rib and anteriorly, the parietal pleura is approximately at the level of the 8th rib. Posteriorly, the 12th rib curves downward, yet the pleura continues in a relatively horizontal plane, crossing the 12th rib at the lateral border of the erector spinae muscles of the back. In some individuals, the 12th rib is difficult to palpate through the subcutaneous layers, making accurate identification on physical exam difficult [6].

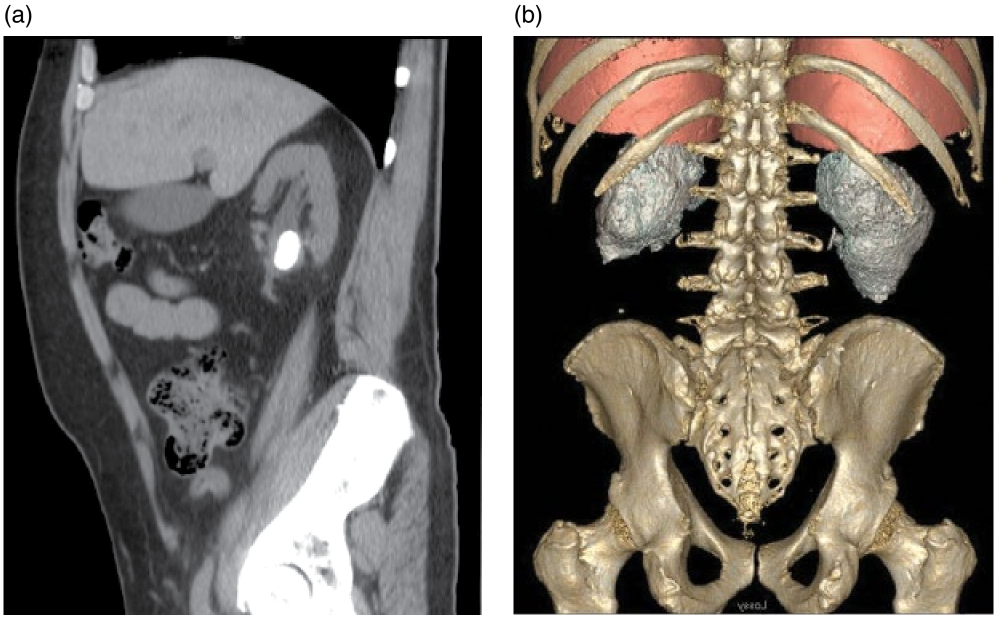

**Figure 34.1** Relationship of the kidneys, pleura, and ribs. (a) CT image in sagittal section showing the pleural reflection extending down to the 12th rib. Notice that supracostal access would violate the pleura in this patient. (b) Three-dimensional CT reconstruction of the same patient showing the relationship of the pleura, ribs, and kidneys. The parietal pleura has been colored pink, and the kidneys are gray. Notice that the pleura crosses the 12th rib approximately half-way along its length.

The relative levels of the kidneys and parietal pleura in relation to the ribs means that in many patients the superior aspects of the kidneys are covered by parietal pleura posteriorly [6]. This relationship is an important consideration since many urologists approach percutaneous surgery of the kidney from the posterior aspect.

## Incidence, etiology, and risk factors of thoracic complications

Percutaneous nephrolithotomy techniques have improved since the early descriptions, with modern data showing an incidence of Clavien grade III or higher complications of about 5% [8–10]. There is variability in the reporting of thoracic complications. Some studies report all complications detected, many of which are incidentally discovered on postoperative imaging, while others report only complications that were diagnosed based on symptoms. One multicenter study reported the outcomes of 197 patients who underwent PCNL and showed that 111 (56%) had CT evidence of chest pathology on routine follow-up imaging. However, 88 of these were atelectasis that resolved with conservative measures and only one patient required a chest tube for a hydrothorax [11]. Nevertheless, thoracic complications constitute a significant percentage of the overall complication rate following percutaneous renal surgery with an incidence of 1.8–3.1% [8–10, 12]. The etiology of thoracic complications involves the introduction of air or fluid into the pleural space during or following the procedure.

The proximity of the kidneys to the diaphragm and pleura directly correlate to the risk of thoracic complications. Therefore, the risk of injury to the pleura increases with higher intercostal space access to the kidney. Table 34.1 shows the results of selected studies demonstrating the risk of thoracic complications in relation to the level of access. Munver et al. categorized thoracic complications by site of entry, showing a rate of pleural injury of 4.5% for subcostal access versus 16% for supracostal access. In the supracostal group, 35% of the patients with access above the 11th rib had a pleural injury [13]. Lojanapiwat and Prasopsuk reported a 15.3% hydrothorax rate for supracostal access versus 1.4% for subcostal access. However, only 10 of these patients required drainage. In contrast, nine (5%) of the patients in the supracostal group required drainage [14]. The Clinical Research Office of the Endourological Society (CROES) published data from 5803 patients across 96 worldwide centers showing an overall rate of thoracic complications of 1.8%, all of which were hydrothoraces [10]. These data were then analyzed to evaluate the risk of thoracic complications between patients with upper pole access versus patients with lower pole access. The upper pole access group had a hydrothorax rate of 5.8% whereas the lower pole access group had a hydrothorax rate of 1.5%. This equated to a hydrothorax odds ratio of 0.4 (0.19–0.85) for lower pole versus upper pole access.

The odds ratio of hydrothorax for access above the 11th rib versus above the 12th rib was 5.6 (1.97–15.8) [15].

These data have led some surgeons to prefer lower pole access when possible as it has a much lower rate of thoracic complications and flexible nephroscopy can be used to treat upper and middle calyceal stones [22]. Proponents of upper calyceal access cite improved access to the ureter and better stone clearance rates. Upper pole access is often preferred to treat urinary stones in the proximal ureter, stones associated with UPJ obstruction, upper calyceal diverticulum stones, renal anomalies, and complex staghorn stones [14, 15, 23]. However, the benefits of upper calyceal access must be weighed against the risk of thoracic complications, as upper calyceal access requires a supracostal approach in approximately 70% of patients [15].

When access superior to the 12th rib is preferred, staying lateral to the midscapular line may reduce the risk of pleural injury. Recall that the 12th rib curves downward, while the pleura maintains a mostly horizontal course along the posterior chest. Therefore, staying lateral to the paraspinal muscles may allow supracostal access while decreasing the incidence of pleural injury.

Another risk factor for the development of a hydrothorax is premature withdrawal of the percutaneous access sheath. The percutaneous renal access sheath offers several advantages, it diverts urine and irrigation from the renal collecting system through the center of the sheath and out of the body. This helps to decrease the intrarenal pressures while operating and helps to minimize extravasation of fluid out of the kidney into the retroperitoneum. In terms of thoracic complications, if a pleural injury occurs and fluid is allowed to extravasate, this can travel through the pleural defect and accumulate in the pleural space. This can be done inadvertently when the nephroscope is withdrawn during the procedure.

Therefore, care must be taken to ensure that the sheath is not displaced during the surgery. Occasionally the sheath is withdrawn to allow access to nearby calyces. It is recommended that this be done near the end of the procedure to help minimize any extravasation that may occur.

There does not appear to be a significant difference in the rate of thoracic complications for access obtained by a urologist versus a radiologist. El-Assmy et al. performed a retrospective review of 1121 PCNL surgeries; 661 (52%) were obtained by a urologist at the time of the PCNL and 612 (48%) were obtained by an interventional radiologist prior to the PCNL. There were two hydrothoraces requiring drainage in the cohort, with one being in the urologist access group and the other in the radiology access group. The small numbers of pleural complications did not demonstrate statistical significance between the groups. Interestingly, the urologist group used multiple access points in 230 of the cases and performed a supracostal access in 112 (17%) of the cases. In contrast, the radiologist access group obtained supracostal access in only 29 (4.7%) of the cases [24]. Watterson et al. performed a retrospective review during a similar time frame. The study included 103 patients with 54 patients who had access obtained by an interventional radiologist and 49 patients who had access obtained by a urologist. Again, each group demonstrated one pleural complication during the study which did not show a statistical significant difference between the urologist-guided group versus the radiologist-guided group [25]. In studies of this nature, one criticism is that interventional radiologists may be asked to obtain access in the more complicated patients. In addition, in some of the patients who had access obtained by interventional radiologists this may have been done to drain the kidney and not necessarily to access the kidney in a way to best treat the offending stone. However, it is notable that in both studies mentioned, the urologists obtained a higher number of accesses and in the El-Assmy study did so using a supracostal approach and yet maintained the same complication rate.

The risk of bleeding and hemothorax is similarly increased by supracostal access as thoracic bleeding is often caused by intercostal vessels. Since the neurovascular bundle runs just inferior to each rib, if supracostal access is used, needle access should be done on the superior aspect of the rib below to minimize bleeding [26]. Multiple puncture sites have also been shown to have a higher incidence of bleeding, which may contribute to a hemothorax [17].

There are data to support that operative time, fluoroscopy time, and even overall complication rate decreases with surgeon experience. However, it is unclear if the rate of thoracic complications specifically is affected by surgeon experience [27–29]. There does not seem to be a correlation between dilation method and rate of thoracic complications [30].

Body mass index (BMI) does not appear to have an impact in thoracic complications. Fuller et al. analyzed the CROES database and found no difference in pulmonary complications in relation to patient BMI [31]. Other studies have also corroborated these results [32, 33], and some data have even shown that increasing BMI corresponds to a lower risk of thoracic complications [16]. This is likely because the higher amounts of visceral fat push the kidneys more cephalad, thus creating a greater distance between the diaphragm in the collecting system. Patients who have certain anatomic variations such as horseshoe kidney, pelvic kidney, and malrotation tend to have lower risks of thoracic complications as the kidney is located more caudad [34]. In a study of 54 cases done on horseshoe kidneys, none of them experienced a thoracic complication [35].

Special consideration should be given to patients that have alteration of normal anatomical landmarks such as patients with severe scoliosis, spinal cord injury, and other musculoskeletal deformities. It is often difficult to position these patients on the operating table and the relationship of the pleura to the kidneys is often distorted due to their physical deformities. CT or ultrasound imaging should be considered when obtaining access in these patients to decrease thoracic complications [36].

The risks of a thoracic complication are higher when upper pole access is used as this often violates the pleura. However, this approach offers many ergonomic advantages and allows for superior access for a multitude of conditions. The risks of upper pole access must be carefully weighed against the benefits of this approach. Each patient should be assessed for the optimal access carefully and no one approach will work for every patient.

## Descriptions of thoracic complications

### Pneumothorax

Pneumothorax is the accumulation of air within the pleural space (Figure 34.2). A pneumothorax results from the introduction of external air into the pleural space as a result of a pleural violation during surgery. Most commonly this occurs during the surgical procedure as air is introduced during renal access or tracks along the access sheath during the procedure. In this instance the source of the air is from outside of the patient's body. Rarely, injury to the lung parenchyma can occur when obtaining percutaneous renal access. This can result in a tension pneumothorax where air continues to escape from the bronchial tree or alveoli that

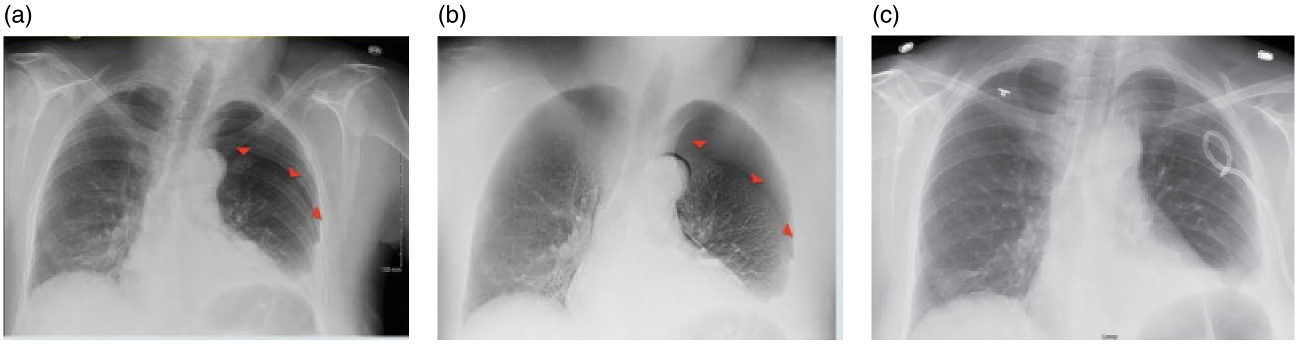

**Figure 34.2** Pneumothorax. (a, b) Chest X-rays of the same patient in different windows showing a pneumothorax. Arrowheads mark the edge of the lung parenchyma. Notice the lung parenchyma does not extend to the chest wall and there is a significant collection of air superior to the lung. (c) Chest X-ray of the same patient after placement of a chest tube with resolution of the pneumothorax.

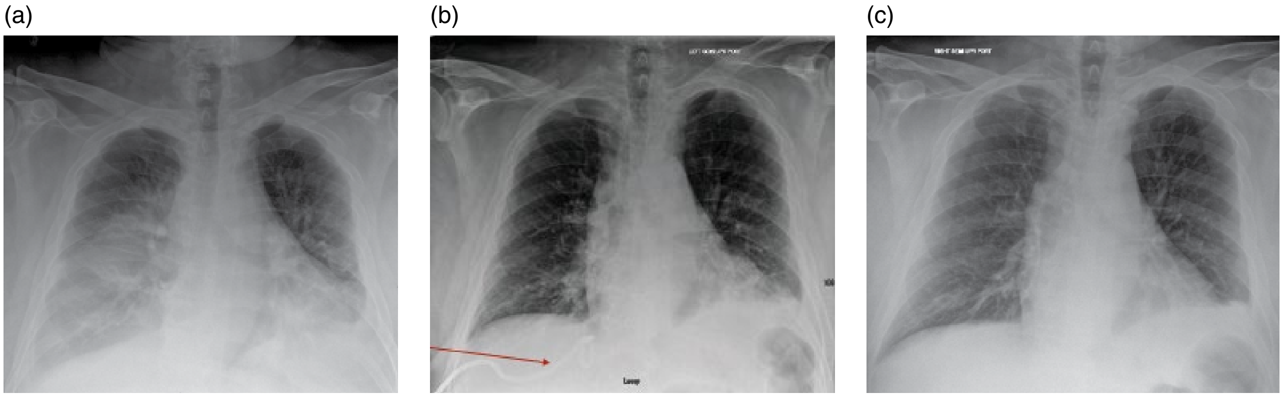

**Figure 34.3** Hydrothorax. (a) Chest X-ray showing blunting of the costophrenic angle with fluid. The patient had undergone right PCNL the day prior via an upper calyceal access. He was experiencing significant pleuritic chest pain and requiring 15 l/min of supplemental oxygenation. (b) The same patient after insertion of a pigtail chest tube in the dependent portion of the pleural cavity (arrow). The patient ultimately drained approximately 1.5 liters of fluid from the thoracic cavity. The creatinine was similar to the patient's serum creatinine and no bacteria were demonstrated on Gram stain or culture. (c) Chest X-ray after two days of chest tube removal, demonstrating resolution of the hydrothorax. Notice the presence of a clear costophrenic angle and the clear demonstration of lung markings that continue to the edge of the chest wall.

becomes trapped in the pleural space. Both etiologies can generate a compressive effect against the lung parenchyma if air continues to accumulate in the relatively fixed space of the thoracic cavity.

## Hydrothorax

Hydrothorax is the accumulation of fluid within the pleural space (Figure 34.3). The fluid can be a variety of substances, including surgical irrigation, urine, or reactive serous fluid. In the case of surgical irrigant or urine, the fluid extravasates through the dilation tract of the kidney and subsequently passes through the pleural defect caused by the percutaneous access and into the pleural space. Urine can accumulate in the pleural space during or after the procedure and is referred to as a urinothorax. If the collection of urine continues to re-accumulate through a fistulous connection, this is referred to as a nephropleural fistula. This connection allows for urine to continue to fill the pleural space. Although this is a less common form of hydrothorax, Lallas et al. reported a rate of 2.3% [37].

Occasionally, serous fluid can accumulate within the pleural space as a result of a reactive effusion. This results from irritation of the diaphragm that occurred during the surgical procedure or from a nephrostomy tube that was placed at the end of the procedure, causing a reactive serous fluid accumulation in the pleural space.

## Hemothorax

Hemothorax is the accumulation of blood in the thoracic cavity. This is most commonly the result of injury to an intercostal vessel which causes bleeding that can accumulate in the pleural space [26]. Alternatively, bleeding emanating from the kidney itself can traverse through a

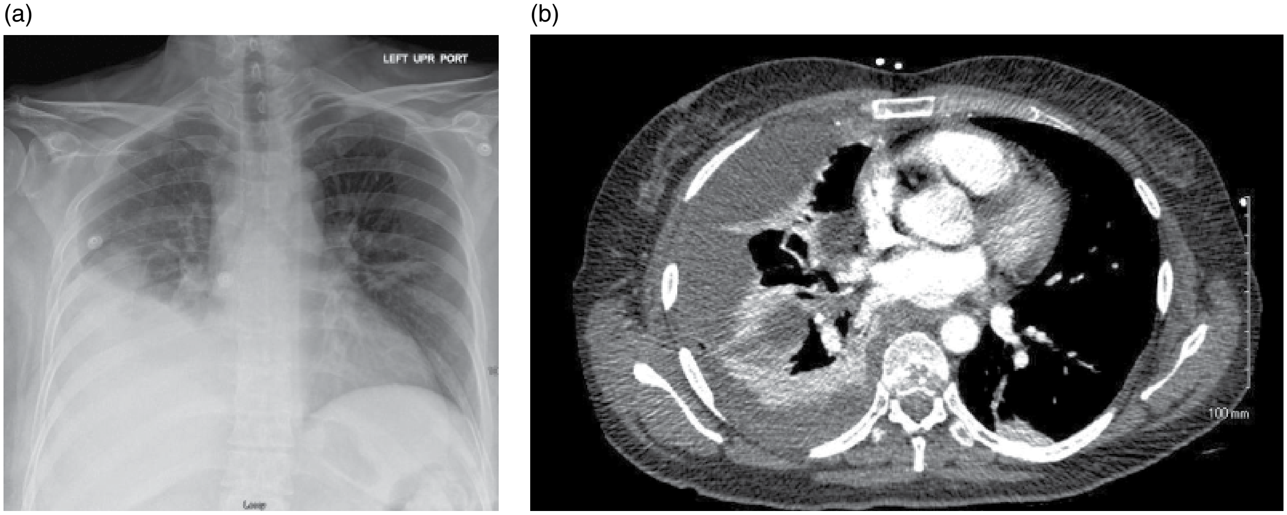

**Figure 34.4** Empyema. (a) Chest X-ray and (b) chest CT from a patient with a history of pyelonephritis who underwent right PCNL for a staghorn calculus. The patient later developed leukocytosis, fevers, and had purulent fluid emanating around her nephrostomy tube. A chest tube was placed with return of pus. Notice on the chest X-ray the dense accumulation of fluid obscuring the right lung. The CT of the chest demonstrates a dense, loculated, fluid collection with areas of enhancement indicative of a complex empyema. The patient failed to respond to chest tube drainage alone and video-assisted thoracic surgery was performed with subsequent improvement in clinical status.

pleural violation and accumulate in the thoracic cavity [27]. Hemothoraces may present immediately at the end of the case after the sheath is removed or in a delayed fashion, depending on the etiology of the bleeding.

### Empyema

Empyema is the presence of pus within the pleural space (Figure 34.4). This can occur either as a secondary infection of sterile fluid that enters the pleural space or as a result of infectious fluid that accumulates within the pleural space. In the former example, an uncomplicated hydrothorax or hemothorax may become infected if bacteria are able to take up residence and replicate within the fluid. In the later example, infected fluid extravasates from the kidney and enters the pleural space. The treatment of renal stones also has a known risk of releasing any bacteria that are associated with the stone being treated. These bacteria may then travel via surgical irrigant and/or urine into the pleural space, where they can grow and result in an empyema. An empyema may also result from a nephropleural fistula if associated with a urinary tract infection [26].

## Diagnosis of complications

The symptomatology and sequelae of thoracic complications can vary depending on the amount and type of fluid that accumulates as well as the patient's overall health status. The thoracic cavity is confined by the boney rib cage, which limits its ability to expand. Therefore, accumulation of air or fluid causes compression of the lungs which can compromise respiratory function. This results in the typical symptoms that are seen with thoracic complications.

The diagnosis of most thoracic complications is based on a combination of clinical symptoms and chest radiology. Complications can be detected intraoperatively or postoperatively depending on the timing of the complication and the severity.

### Intraoperative signs of thoracic complications

There are several changes that may be noticed during the procedure that can indicate a thoracic complication is occurring. Urologists should communicate to their anesthesia colleagues to be cognizant for any changes in ventilation, such as an increase in peak airway pressures [8]. Since the ribs create a relatively fixed structure to the chest wall, any additional air or fluid accumulation compresses the internal organs of the chest, most notably, the lungs. This is particularly problematic when the patient is in the prone position, as expansion of the thoracic cavity is limited in this position and the patient's weight further reduces the expansive capability of the chest wall. Furthermore, when the patient is in the prone position, it is difficult to observe any expansion of the thoracic or abdominal cavity. Narrowed pulse-width pressures may be noticed during hemodynamic monitoring as a result of air or fluid compressing venous return to the heart.

When venous return is compromised, the stroke volume of the heart is decreased, causing a decrease in the systolic blood pressure. This creates a smaller gradient between the systolic and diastolic blood pressure, thus creating a lower pulse pressure difference.

If a nephrostomy tube is placed at the end of the procedure, many urologists inject contrast to ensure proper placement. If contrast is seen communicating with the pleural space, this indicates that a pleural violation has occurred [8].

## Radiologic diagnoses of thoracic complications

Radiologic evaluation of the patient after the procedure is recommended, especially after upper calyceal access [26]. Some urologists perform intraoperative imaging of the chest at the conclusion of the procedure to evaluate for thoracic complications, while others delay chest imaging until the recovery room. Ogan et al. evaluated intraoperative chest fluoroscopy versus postoperative chest X-ray versus postoperative chest CT and found that intraoperative chest fluoroscopy is sensitive enough to detect clinically significant thoracic air or fluid accumulations [38]. Performing intraoperative radiographs has the advantage that if a significant intrathoracic air or fluid collection is encountered, percutaneous aspiration or the placement of a chest tube can be accomplished while the patient is under anesthesia [39].

Alternatively, chest imaging can be obtained in the recovery room. Plain chest radiography is less sensitive than transthoracic ultrasound or chest CT, however, it is less expensive and usually readily available. Furthermore, it can usually detect clinically significant amounts of air or fluid.

Chest X-rays can detect as little as 50 ml of fluid in the lateral view, whereas volumes of 200 ml are typically needed to view blunting of the costophrenic angle on anteroposterior films, and the diaphragm becomes obscured at a volume of 500 ml [26, 38]. Ultrasound may also be used to evaluate for pleural fluid accumulation and can visualize as little as 50 ml of fluid [26]. CT scan is the most sensitive modality, however this is the most costly of the imaging techniques. In addition, the small air and fluid accumulations it detects may not require intervention and can often be safely observed. Semins et al. reported on 197 patients who underwent PCNL and had a CT scan within 24 hours of surgery and found that 23 patients (12%) demonstrated a pleural complication. However, only one of these patients required a chest tube and the remaining recovered with conservative measures [11]. Therefore the increased sensitivity may not be necessary and certainly introduces an increased cost and radiation exposure and may complicate the management of these pathologies [38].

## Symptoms of thoracic complications

Patients with a thoracic complication may complain of pleuritic chest pain or shortness of breath and may demonstrate hypoxia or decreased breath sounds on the affected side [8]. These symptoms should be closely followed and imaging should be performed (if not done already) to evaluate for thoracic pathology.

## Differentiating between thoracic pathologies

A pneumothorax can be easily differentiated from forms of hydrothoraces by the presence of air in the pleural space. Air appears black on plain radiographs and CT and in the case of pneumothorax will often rise to the most superior position of the chest, which can vary depending on the position of the patient. The lung parenchyma will typically demonstrate dense linear markings that normally extend to the periphery of the chest wall. When there is a gap between the chest wall and the lung parenchyma this indicates a pneumothorax is present. Figure 34.2 shows an example of a pneumothorax.

Hydrothoraces will demonstrate a hazy appearance in the dependent portion of the chest that obscures the costophrenic angle of the pleural reflection as it continues from the lateral chest wall onto the domed shape of the diaphragm. The relative position of the fluid will vary depending on the patient's position. Figure 34.4 shows an example of a hydrothorax.

Differentiating between types of hydrothorax may require aspiration of the pleural fluid. Visually, the fluid can be assessed and one can differentiate between simple-appearing fluid, blood, or frank pus. If simple fluid is encountered, this should be sent for creatinine, Gram stain, and culture. If the fluid creatinine is higher than the serum creatinine, this indicates the presence of urine in the fluid. The Gram stain and culture can determine if there is a concomitant infection in the fluid even if there is not frank pus. If there are findings consistent with infection, an empyema may develop and this can affect management (see Figure 34.4). We discuss this in detail in the section on Management of thoracic complications.

If a urinothorax is diagnosed, one must consider if this was urine that accumulated during the procedure or if a nephropleural fistula is present. The diagnosis of a nephropleural fistula is more likely when the patient has a delayed presentation of fluid. In addition to the diagnostic techniques mentioned earlier, a few other modalities may be helpful in this diagnosis. As previously mentioned, if a nephrostomy tube is still present, a nephrostogram may demonstrate extravsation of contrast from the collecting system into the pleural space.

A retrograde pyelogram may also be beneficial in the evaluation, diagnosis, and management of nephropleural fistula, particularly when there is no nephrostomy tube. Contrast extravasation may be seen extravasating from collecting system into the pleural space in a similar fashion to the findings seen on antegrade nephrostogram. If a nephropleural fistula is diagnosed, the patient should be evaluated for distal obstruction such as from a distal stone fragment or edema [26]. CT, kidney–ureter–bladder, retrograde pyelogram, or a nephrostogram may be useful in this evaluation. If an obstruction is demonstrated, this kidney should be drained, as discussed in the section on Management of thoracic complications.

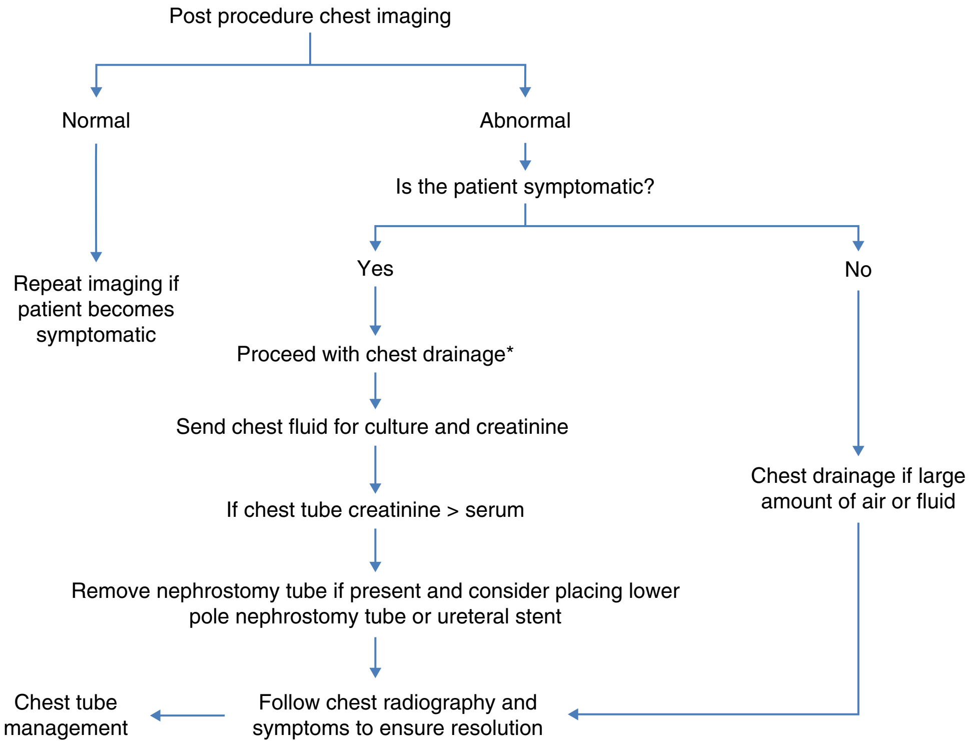
Hemothorax is diagnosed by radiographic evidence of blood in the pleural space or by visualizing blood upon aspiration of the thoracic fluid collection. Bleeding may be noticed during the procedure which can raise the suspicion of a hemothorax if a fluid collection is demonstrated postoperatively. In addition, a decrease in the patient's hemoglobin and hematocrit may also serve as a clue that bleeding has occurred. Significant bleeding may also be noticed once the sheath is removed during the procedure. The source of bleeding may be from an intercostal vessel or from the kidney itself. While the source of bleeding may not be entirely clear, the urologist should be aware that this bleeding may track into the pleural space if pleural violation has occurred.

Fluid, pus, blood, urine, and air can all accumulate within the pleural space after PCNL. These can be differentiated based on a combination of clinical history, radiology and visualization of the fluid. Figure 34.5 shows a diagnostic algorithm that illustrates this process.

## Management of thoracic complications

The management of thoracic complications is largely determined by the patient's clinical status. Small volume of air and fluid in the pleural space may be observed when the patient is minimally symptomatic. Intervention is therefore indicated if the patient is having significant symptoms, or when significant volumes of air or fluid are seen [9]. Figure 34.6 demonstrates a management algorithm for thoracic complications following percutaneous renal surgery.

Chest drainage is the treatment for thoracic complications. The type and size of the chest tube depends on the pathology being managed. Small chest tubes are usually adequate to drain air and simple fluid collections, whereas larger tubes may be needed to optimally drain hemothoraces and empyemas [40]. Chest tubes are



Post procedure chest imaging

Chest drainage if large amount of air or fluid
Follow chest radiography and symptoms to ensure resolution
Chest tube management

**Figure 34.6** Management algorithm for thoracic complications following percutaneous renal surgery. *If blood or pus is present, consider placing a larger bore chest tube. Consider early consultation with thoracic surgery. Chest tube removal: pneumothorax – consider trial of water seal for 6 hours to evaluate for recurrent pneumothorax; hydrothorax – can remove if chest tube drainage <300 ml per day.

typically placed to continuous suction at about 20 cm$H_2O$ and are flushed with small volumes of saline every 6 hours to minimize the risk of tube occlusion and ensure drainage. If clinical improvement is not seen after about 24 hours of drainage, imaging, such as CT or ultrasound, should be utilized to ensure appropriate placement. If the tube is in the correct location without improvement in the collection, consideration should be given to increasing the size of the chest tube [41]. Some urologists place their own drainage tubes, especially if this is done intraoperatively, while others refer this to an interventional radiologist, general surgeon, or a thoracic surgeon [39].

Once a chest tube is placed, the patient is followed clinically for resolution of symptoms. Serial chest radiography is often used as well to determine the duration of drainage and to ensure that the drainage modality is adequate.

## Hydrothoraces

Symptomatic or large hydrothoraces typically require chest tube drainage. The size of the chest tube and duration of drainage vary depending on the type and size of the hydrothorax. The role of aspiration alone in the management of hydrothoraces is poorly defined. If a small collection is diagnosed while the patient is under anesthesia, some favor aspiration alone. This offers the ability to differentiate the etiology of the hydrothorax. In addition, aspiration alone is less morbid to the patient than an indwelling chest tube. The concern with this approach is if the collection reaccumulates, the patient then needs to undergo a separate procedure. In addition, small collections can often be observed, meaning that some of the aspirations may not be required. The viscosity and visual assessment of fluid can be done on the initial aspiration during placement of the chest tube. If simple fluid or urine is detected, this may be adequately drained with smaller bore chest tubes. However, if pus is returned, a large-bore chest tube may be useful [40]. It is recommended that the chest tube aspirate be sent for creatinine and culture to aid in the diagnosis as mentioned earlier. If the culture demonstrates an infection or if there is clinical concern for infection, antibiotics should be initiated if they have not been already. The patient is followed for resolution of symptoms and serial chest radiographs are obtained to monitor resolution of the fluid collection. Once resolution has been documented, the chest tube may be removed.

## Empyemas

Empyemas can be difficult to treat and may not resolve with chest tube drainage alone as the purulent fluid can be quite thick. Furthermore, empyemas can become loculated, making them resistant to tube drainage. The use of fibrinolytics has been described for some time now in the treatment of empyemas with mixed results. The options for fibrinolytic therapy are: streptokinase, urokinase, tissue plasminogen activator (t-PA) or human recombinant deoxyribonuclease (DNase). Several small studies have shown benefits of using these agents, but larger studies and meta-analyses showed no statistical benefit for fibrinolytics over chest tube drainage alone [41, 42].

Surgical drainage is recommended in patients who fail chest tube drainage or for the primary treatment of patients with loculated or thick fluid on imaging [42, 43]. Surgical drainage can be accomplished via endoscopic approaches or open surgical drainage. Typically, minimally invasive endoscopic approaches can be used. In a small prospective randomized trial, early surgical drainage was associated with a higher treatment success rate, fewer days of chest tube drainage, and shorter hospital stay. Therefore, thoracic surgery consultation should be obtained early in the management of empyema [44].

Video-assisted thoracic surgery (VATS) may be used as a minimally invasive management of empyema or complicated hemothorax. VATS is similar to laparoscopy for the thoracic cavity. The patient is typically placed in the lateral decubitus position. A small incision is made between the ribs on the lateral aspect of the chest wall. Dissection is carried down through the subcutaneous layers and into the parietal pleural layer in order to enter the pleural space. Care is taken to avoid injury to the underlying lung during this process. The surgeon's finger is then used to free a space into which the trocar can be placed into the thoracic cavity. Occasionally the ipsilateral lung is deflated during the procedure using a dual-lumen endotracheal tube. This allows for an increase in working area in the thoracic cavity. A trocar is then inserted through the incision and a camera is used to inspect the surgical field. Because the chest wall is supported by the ribs, insufflation may not be required, although it is used by some surgeons. Other trocars can be placed under direct vision in the intercostal spaces in a manner similar to laparoscopy, or small incisions may be made and traditional surgical instruments can be inserted through the chest wall for use. A combination of suction and dissection is then used to remove the infected tissue while attempting to minimize injury to the lung tissue. A chest tube is placed at the end of the procedure to allow the lung to expand [45]. Open drainage is rarely required when minimally invasive approaches fail and typically requires consultation with a thoracic surgeon [41].

## Reactive effusions

Reactive effusions typically resolve spontaneously with time. If a nephrostomy tube has been left in place, this should be removed to eliminate the diaphragmatic irritation.

## Nephropleural fistulas

Nephropleural fistulas typically resolve with placement of chest tube and urinary drainage with a ureteral stent or a nephrostomy tube [27, 37]. If the patient has persistent drainage after placement of the ureteral stent, anticholinergics may be used to decrease bladder spasms or a Foley catheter may be placed to facilitate maximal drainage of the urinary system [26]. These typically resolve within 12 hours; however, prolonged periods of leakage can occur in 1.5–4.6% of patients [46]. If a Foley catheter was used to facilitate drainage, this can be removed once the drainage stops accumulating in the thoracic cavity [26].

The nephrostomy tube itself can be an exacerbating factor in hydrothoraces. If the nephrostomy tube traverses the pleura, urine can extravasate and course along the tube into the thoracic cavity. In this instance, removing the nephrostomy tube will aid in pleural closure and healing. If there is a concern for pleural violation at the time of surgery, placement of a lower pole nephrostomy tube can drain the kidney while allowing the pleural violation to heal [47].

## Hemothoraces

Hemothoraces are treated in a similar manner as other hydrothoraces. However, like empyemas, the fluid collection is typically quite thick and may require the use of a larger bore chest tube. Furthermore, the urologist must determine if the source of bleeding is ongoing. If there is evidence of continued, symptomatic bleeding, the urologist should consult regarding angioembolization of the bleeding.

## Pneumothoraces

Pneumothoraces may be observed when small and the patient is minimally symptomatic. If the patient is experiencing significant pleuritic pain, decreased oxygen saturations, shortness of breath, or has failure of the pneumothorax to resolve on chest radiography, a chest tube should be placed. The PCNL-associated pneumothorax is typically caused by air that is introduced at the time of the procedure. This etiology differs from a pneumothorax caused by injury to the lung itself or after thoracic surgery. In these instances, the air enters the pleura from the bronchial tree and continues to accumulate in the pleural space until the lung itself heals. However, direct injury to the lung is extremely rare in the case of PCNL. The chest tube is placed initially to provide wall suction until the pneumothorax resolves radiographically and the patient's symptoms improve. There is some debate whether a trial of water seal is necessary prior to removing the chest tube or if the chest tube may be removed while on suction. However, there is no clear consensus in the thoracic literature. The reason for performing a trial of water seal is to decrease the risk of recurrent pneumothorax after the chest tube is removed. The use of water seal may be of more importance when managing pneumothoraces versus other thoracic pathologies [48, 49]. Once the pneumothorax has resolved, the chest tube may be removed as previously described.

### Chest tube management

Chest tubes can typically be removed at the bedside depending on the comfort level of the patient. It maybe helpful to administer analgesics prior to tube removal, as the process can be painful. There is debate with no clear consensus as to whether the chest tube should be removed during inspiration or expiration. Prior to removing the chest tube, the securing suture should be cut and an occlusive dressing should be prepared. This is placed over the thoracostomy site prior to removing the chest tube. Once the dressing is in place, the tube is swiftly removed and the dressing secured in place with tape [40, 50].

The management of thoracic complications depends on the severity of the symptoms the patient is experiencing. Small pneumothoraces and hydrothoraces can generally be observed, especially if the patient is asymptomatic or minimally symptomatic. If the patient has a "large" pneumothorax or hydrothorax, this should be treated even if the patient is not experiencing significant symptoms. Aspiration may be considered for small hydrothoraces while a temporary chest tube is better suited for pneumothoraces and larger hydrothoraces. A larger bore chest tube is recommended to treat hemothoraces and empyemas. Hemothoraces and empyemas should be closely followed as they have a higher risk of developing into more complicated and loculated collections. It is prudent to involve the expertise of a thoracic surgeon in these cases to evaluate if the patient would benefit from early surgical evacuation.

## Prevention

Benjamin Franklin once remarked, "An ounce of prevention is worth a pound of cure." Performing percutaneous renal surgery carries with it certain risks, however, these should be minimized when possible. Careful patient selection and access planning is paramount in minimizing risks of thoracic complications. The most important aspect of minimizing complications is deciding when the benefits of upper pole access outweigh the risks associated with this. If it is decided that supracostal access is preferred, there are several techniques that can lower the incidence of clinically significant thoracic complications.

Needle access should be obtained in full expiration in order to decrease the amount of pleura and diaphragm that lies over the kidney [7, 23, 26]. If the 10th or 11th intercostal space is used for access, placement of the needle lateral to the midscapular line can help to minimize injury [7]. Another technique that has been used to is to place a needle or a small-caliber sheath into the lower aspect of the kidney in order to displace it inferiorly.

The use of a percutaneous access sheath throughout the entire procedure is recommended. This will serve to divert most of the urine and irrigation out of the body, which will minimize any accumulation in the chest. It is also important to ensure that the access sheath remains in the collecting system throughout the procedure. If the sheath is withdrawn from the collecting system, this may allow fluid to flow into the retroperitoneum and possibly the thoracic cavity [26]. Furthermore, the percutaneous access sheath serves to maintain a low intrarenal pressure. If this is not done, the intrarenal pressure can increase, causing extravasation of fluid which can accumulate in the thoracic cavity. Some had advocated for the use of a ureteral access sheath during PCNL. This can serve to further minimize the intrarenal pressures and minimize hydrothorax [51, 52].

Prompt removal of a nephrostomy tube is wise if there is concern about pleural violation as air and fluid can track along the tube into the pleural space. In addition, the presence of a tube will discourage the closure of the pleural defect.

## Conclusions

Percutaneous renal surgery is an effective modality with a relatively low rate of complications overall, yet thoracic injury accounts for a percentage of these complications. The endourologist must therefore be aware of the relevant anatomy, make careful selection with regard to access planning, and utilize techniques that minimize complications when performing percutaneous renal surgeries. When complications do arise, a prompt and accurate diagnosis will help the urologist to determine the appropriate management. Understanding the incidence, diagnosis, and management of these complications allows for better shared decision-making between the patient and the provider and for optimal care during the perioperative period.

## Overall complications

Complications of percutaneous nephrolithotomy (PCNL) are common and may occur in 12.5–20% of patients, but they typically are low grade with less than 4% of patients experiencing a Clavien grade III or higher [1–3]. Although rare, solid organ injuries associated with PCNL are among the most feared. While some may be managed conservatively (Clavien grade II), there is significant risk of subsequent intervention (Clavien III or higher) [1]. Although complications such as extravasation, fever, and transfusion are more common, solid organ injury (including colon, bowel, lung, liver and spleen) are fortunately rare, historically occurring in less than 1% of cases [4]. In a 2012 review, Seitz et al. found the overall incidence of organ injury (including liver, spleen, and bowel) to be 0.4%, while thoracic complications occurred in 1.5% of patients [5]. Although various risk factors for organ injury exist, the most unifying may be access through the 10th intercostal space and/or anterior to the posterior axillary line [5]. In this chapter we review the occurrence of organ injury during PCNL, including discussion of diagnosis and management.

## Colon injury

Colon perforation at the time of PCNL is uncommon, occurring in less than 1% of procedures [5–9]. In a review of the literature, Ozturk identified 36 colonic injuries among 9996 cases (0.36%) [7]. The colon is typically positioned anterior or anterolateral to the kidney, and in this orientation risk of injury occurs with extreme lateral access to the kidney, beyond the posterior axillary line. Thus, with normal anatomy, the risk of injury is low. However when abnormal anatomy is present, namely a retrorenal colon, the risk increases.

Anatomic studies have found that a retrorenal colon exists in between 0.6% and 2% of patients, and is more common on the left side (Figure 35.1) [10–14]. This risk may be markedly higher in patients with abnormal anatomy, such as severe spinal scoliosis, where retrorenal colon was identified in up to 25% of patients [15]. Additional risk factors may include chronic constipation and bowel distention, such as in elderly patients, previous surgery or neurologic impairment resulting in neurogenic bowel, prior renal surgery [14, 16], or horseshoe kidney and renal ectopia [9, 17]. Preoperative cross-sectional imaging will help identify high-risk patients and will allow the surgeon to plan their access in order to avoid colonic injury. For patients with severely altered anatomy with narrow windows of puncture, consideration should be given to CT-guided access in order to avoid colon injury.

Early diagnosis of colonic perforation is key to preventing more serious infectious complications. A nephrostogram during the case may demonstrate contrast within the colon, at which time drainage may be established. Postoperatively, the presence of diarrhea, hematochezia, or passage of gas or fecal material through the nephrostomy may all indicate injury. Intraoperative or postoperative imaging with nephrostogram or CT scan is recommended, at which time perforations may be seen. Delayed recognition may increase the risk for infection, including sepsis, and appropriate antibiotic coverage for urinary and colonic pathogens should be implemented.

Treatment of colonic perforation is usually conservative in the absence of peritoneal signs or sepsis [7, 8]. In 1985, LeRoy et al. reported their experience with

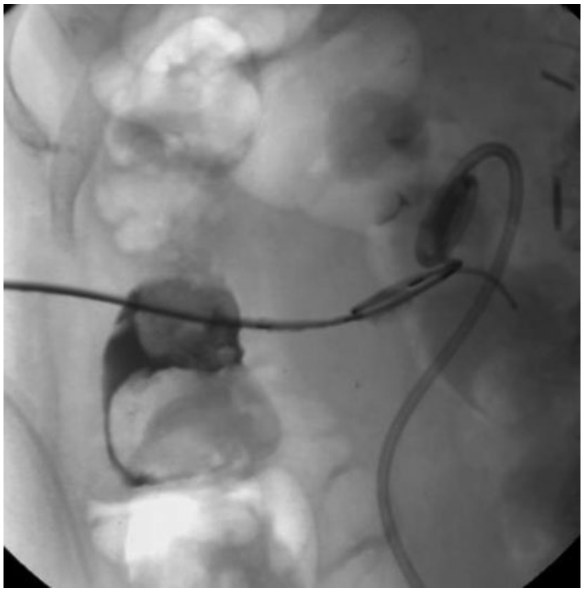

**Figure 35.2** Nephrostogram showing colon injury at the time of left percutaneous nephrolithotomy.

successful conservative management of two patients with colon injury during PCNL [12]. Of the 36 cases identified by Ozturk, a majority were managed conservatively [7]. Conservative management is accomplished by withdrawing the nephrostomy into the colon to serve as colostomy drainage and placing a double-J stent (Figure 35.2). A catheter should be placed into the bladder to create a low-pressure system. Patients should be covered with broad-spectrum antibiotics, and placed on a low-residue diet or alternately on total parenteral nutrition. After 5–7 days, if a colostogram or retrograde pyelogram fails to demonstrate communication between the colon and kidney, the colostomy is withdrawn into the retroperitoneum to serve as a drain. If a barium enema 2–3 days later demonstrates closure of the colon, the retroperitoneal drain can be removed by day 7–10. Patients who develop signs of sepsis or persistent nephron–colonic or colocutaneous fistula should be considered for surgical exploration with diverting colostomy.

## Other bowel injury

Due to the proximity of the second and third portions of the duodenum to the right kidney, injury may occur at the time of PCNL. However such injuries are very rare, with only nine reports of small bowel injury in the literature, including six jejunal and three duodenal injuries [7]. Eight injuries occurred at the time of right-sided PCNL, and one jejunal injury occurred at the time of left PCNL. With the duodenum lying anterior and medial to the kidney, retroperitoneal access should be able to avoid this potentially devastating complication. However, the duodenum may be injured during right PCNL if the renal pelvis is perforated during access or dilation when a needle or instrument is advanced too far. Jejunal injuries may occur in similar fashion. Careful visualization using fluoroscopy at the time of access and dilation may mitigate this risk.

Injury to the small bowel should be suspected if bowel mucosa or bowel contents are visualized along the guidewire or nephrostomy tract. It may also be identified on nephrostogram either intraoperatively or postoperatively. A large injury, signs of sepsis, or peritonitis typically necessitate surgical exploration with open surgical repair. Small perforations in a stable patient without evidence of sepsis or peritonitis may be observed. Of the nine available cases in the literature, seven proceeded to exploratory laparotomy while two were managed conservatively [7]. Conservatively managed patients should have confirmation of a well-draining nephrostomy tube and be placed on bowel rest with nasogastric suction and institution of total parenteral nutrition to allow closure. Follow-up interrogation with nephrostogram and upper gastrointestinal study may be performed 10–14 days after surgery to ensure closure. For example, Al-Assiri et al. report their experience managing a jejunal injury at the time of left PCNL, where an intraoperative connection to the jejunum was found on nephrostogram [18]. The patient had a Malecot catheter placed into the bowel lumen and a double-J stent was placed. The patient was put on total parenteral nutrition with bowel rest, and injection of contrast confirmed closure of the tract between the jejunum and kidney by day 7. After three weeks, the Malecot was removed without need for exploration. In this way, early identification of bowel injury allowed for more conservative approaches, as prompt drainage and initiation of bowel rest may minimize damage. Delayed recognition or large injuries to the small bowel typically necessitate surgical exploration and may be associated with more serious morbidity. However, although conservative measures may be appropriate for some patients, a majority of these rare injuries will require surgical exploration for repair.

## Gallbladder injury

Gallbladder injury during PCNL is a rare but serious complication, with eight reported cases in the literature, all requiring surgical exploration and cholecystectomy [7]. Of these, one case was identified intraoperatively when the gallbladder opacified with contrast, and the others presented with biliary peritonitis. Injury to the gallbladder should be suspected if a greenish discharge is found along the access or if a patient develops signs of peritonitis following a right-sided procedure, in which case a CT scan would be the imaging of choice. Timely diagnosis is important, as biliary leakage may result in profound peritonitis, infection, and scarring with adhesions. All injuries require exploration with cholecystectomy to avoid severe sequelae of this rare complication.

## Lung and pleural injury

Diagnosis and management of thoracic complications of PCNL are discussed in Chapter 34, but a few salient points are worth mentioning here. Hydrothorax and pneumothorax are primarily associated with supracostal access. A CT-based anatomic study by Hopper and Yakes concluded that risk existed for pleural injury with access between the 11th and 12th rib when puncture was performed, even during maximal expiration, with a transpleural puncture occurring 29% of the time on the right and 14% of the time on the left [19]. When puncture was performed between the 11th and 12th rib during inspiration, the pleura would be transversed in most patients. Access above the 10th rib was estimated to result in pleura or lung injury in all patients regardless of inspiration or expiration. These anatomic assessments appear to provide a reasonable estimate, as Munver et al. reviewed their series assessing the risk of injury with supracostal access and found that among 72 patients undergoing access above the 12th rib, the tract was transthoracic but extrapleural [20]. Access above the 11th rib, however, resulted in 19% incidence of hydro- or pneumothorax. Such risk may be decreased by careful inspection of a preoperative CT scan and avoidance of supracostal access where possible. Among patients undergoing supracostal access, surgeons should consider intraoperative or postoperative chest X-ray to assess for thoracic complications.

## Liver and spleen injury

Because of the close proximity of the right kidney to the liver and the left kidney to the spleen, a theoretical risk of injury occurs at the time of PCNL. However such injuries are rare. A 2014 review of organ injury at the time of PCNL identified 11 reports of splenic injury and 1 report of liver injury [7]. A CT-based analysis of the risk of organ injury during supracostal approach found a theoretical risk of splenic injury, which increased the higher the puncture [19]. While there was minimal risk of splenic injury with punctures above the 12th rib done on expiration, this risk rose to 33% for punctures above the 11th rib on inspiration [19]. Such access should be avoided whenever possible and if it is needed, the surgeon should consider CT-guided access. Careful inspection of cross-sectional imaging should precede PCNL so that the surgeon is aware of at-risk structures relevant to their access approach of choice.

Splenic injury should be suspected in the setting of profound hemorrhage, hemodynamic instability or pain out of proportion to the surgery occurring with a left-sided access. However, the presentation may be difficult to diagnose due to the low incidence. CT scan is the imaging of choice (Figure 35.3), but may not always be obtained immediately as patients with excessive bleeding are often sent for angiography in order to perform selective embolization. Of the reported splenic injuries, three were explored with two undergoing splenectomy, and

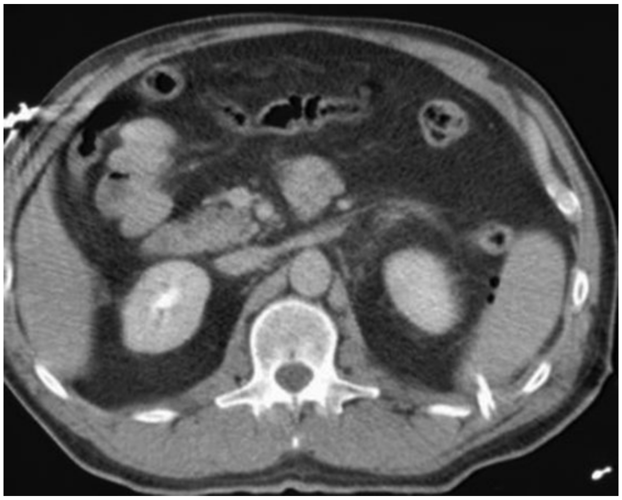

**Figure 35.3** CT scan showing splenic injury at the time of left percutaneous nephrolithotomy.

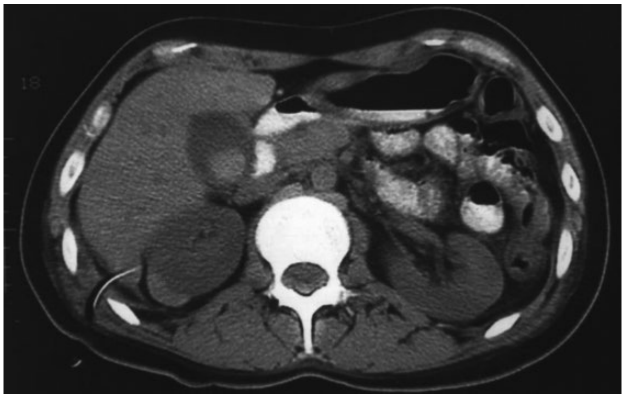

**Figure 35.4** CT scan showing liver injury at the time of right percutaneous nephrolithotomy.

eight were managed conservatively. In the truly unstable patient, exploration and splenectomy may be lifesaving. However, there are multiple reports of successful conservative management of splenic injuries. Thomas et al. report the use of a collagen–thrombin hemostatic sealant down the nephrostomy tract following delayed removal of the nephrostomy tube four days after surgery [21]. In another novel approach, Desai et al. injected Gelfoam pledgets along the nephrostomy tract and placed a ureteral stent, after which the patient had an uneventful recovery [22]. While there is no standard management for splenic injury, conservative options in the stable patient may include close observation, delayed removal of the nephrostomy tube, and novel coagulants down the tract. However unstable patients, or patients who become unstable during a trial of conservative measures, should be prepped for emergent splenectomy.

Liver injury at the time of PCNL is rare, with only one reported case in the literature [7]. Study of anatomic relationships on CT scan predicted minimal risk to the liver with access above the 12th rib, but a 14% risk was found in tracts above the 11th rib [19]. Hepatomegaly may place the patient at risk, particularly if the access takes a more lateral orientation (Figure 35.4), but can usually be avoided with careful inspection of a preoperative CT scan. Fortunately, most liver injuries can be observed and surgical exploration is rare. Conservative measures may include delayed removal of a nephrostomy tube, ureteral stenting to avoid fistula, and use of coagulants along the tract.

## Conclusions

Organ injury at the time of PCNL is an uncommon complication, occurring in less than 1% of patients. However it is important that patient informed consent includes discussion of adjacent organ injury. Among these, colonic injury may be the most common. At-risk anatomy, particularly a retrorenal colon, may be identified on preoperative imaging and access planned accordingly to minimize the risk of injury. Fortunately, a majority of colon injuries may be managed conservatively with stenting, withdrawal of the nephrostomy into the colon, and bowel rest. In contrast to colonic injury, small bowel injury is less common and more severe. Although cases of conservative management have been described in the literature, the majority require surgical exploration. Similarly, gallbladder injury is rare, with only eight reported cases, all of which required exploration with cholecystectomy.

Splenic injury may be seen at the time of surgery, or may result in hemorrhage leading to splenectomy. Several reports of conservative management with delayed nephrostomy removal and injection of coagulants down the tract have been described to be successful. However, surgeons should have a low threshold for exploration and splenectomy when needed. Liver injury occurring at the time of right-sided PCNL can typically be managed conservatively and surgical exploration is rarely needed.

Although solid organ injuries are uncommon during PCNL, the risk can be minimized with meticulous inspection of preoperative imaging and careful planning of access. For patients with challenging anatomy, CT-guided access may be considered to minimize risk. Prompt identification and management of solid organ injuries may call for more conservative management, but when these rare complications occur surgeons should be prepared for surgical exploration when necessary.

*Department of Urology, Austin Hospital, Heidelberg, Victoria, Australia*

## Introduction

Percutaneous nephrolithotomy (PCNL) is the gold standard treatment for staghorn stones, large renal stones, and complex renal calculi [1–4]. Since its description and introduction over 30 years ago, there has been continual improvement in PCNL surgery [5]. Technological enhancements and technical advances now mean that the puncture is more accurate and safer than ever, stone clearance is maximal, and the complication rate is low and acceptable [6]. Attention has now turned to decreasing postoperative pain, preventing urine extravasation, and reducing the duration of hospital admission while maintaining excellent stone clearance rates.

Urinary drainage with a nephrostomy tube (NT) has been a part of PCNL surgery ever since Winfield et al. reported serious complications due to early NT removal [7]. Subsequent to this publication, NT placement at the end of PCNL surgery became doctrine and an integral part of postoperative urinary drainage. This occurred despite Wickham et al., several years earlier, publishing that “nephrostomy-free” PCNL was safe and associated with minimal complications in a much larger series [8].

Following this report, the practice was to leave a large-bore NT or re-entry catheter in the PCNL tract. Hunter et al. stated that the NT should only be 2–4 Fr smaller than the nephrostomy sheath, meaning that an NT of 26–28 Fr would be needed for a standard PCNL [9]. The rationale for this was that the large-bore NT would maintain drainage of the kidney, while preventing urinary extravasation and providing hemostasis through compression [10]. However, it soon became clear that NTs this large were not necessary and that smaller NTs would suffice instead of large-bore variants.

As a result, a large collection of drainage tubes was developed to meet the demands of post-PCNL NT drainage. These range from large-bore NTs, such as Councill tip, re-entry Malecot catheters, and Circle tubes, to smaller bore tubes, such as the Coop loop NT, pigtail NT, and the range of nephroureterostomy catheters (NUC). Ultimately, it become apparent that the placement of these tubes at the end of the procedure could actually have a negative impact in the postoperative period, possibly increasing pain, analgesia use, and hospital stay [11–16]. This, coupled with the fact that the main function of NT is only to maintain urinary drainage and does little to prevent bleeding or urine leak, led to the reintroduction of NT-free PCNL surgery [17].

NT-free PCNL surgery has now been termed tubeless or totally tubeless PCNL, depending on whether internal ureteric drainage is utilized. Tubeless refers to NT-free PCNL surgery, where instead of a NT drain, a ureteral catheter or double-J (JJ) stent is placed internally for renal drainage with or without a urethral catheter. Thus ureteric catheters and JJ stents have also been added to the endourologist’s options for post-PCNL drainage. Totally tubeless PCNL surgery is truly tubeless, and at the end of the procedure no NT or internal drainage is utilized. The use of hemostatic agents in the PCNL tract of tubeless and totally tubeless PCNL surgery has been recently described as a potential way to reduce bleeding and may become more regularly utilized following PCNL surgery.

It is the goal of this chapter to examine the rationale behind NT tube placement in PCNL surgery and to review the exit strategies available for this procedure. We review the evidence for large-bore NT, small-bore NT, tubeless PCNL, and totally tubeless PCNL. We also look

at the modifications to each procedure, such as JJ stents with tethers and the placement of hemostatic agents in the PCNL tract.

## Large-bore or small-bore nephrostomy

A large-bore NT is generally regarded as of size ≥18 Fr. Councill tip, Circle loops, and re-entry Malecot catheters are some of the most common large-bore NTs available. Small-bore NTs are ≤18 Fr, and several different varieties also are obtainable [18]. These include Cope loop NT, pigtail NT, and the nephroureterostomy catheter (NUC). All NTs have certain important characteristics, especially perforations or openings to allow drainage. There should also be a self-retaining loop or device to keep the tube in place, as well as an effluent channel to allow urinary drainage out and a tap to which to connect a drainage bag. An example of a small-bore NT is shown in Figure 36.1.

Other important intrinsic features of a NT are its retention strength and flow properties. These are its ability to resist accidental removal and its urinary drainage rate. In a recent study, Canales et al. found the Cope loop NT to be superior to pigtail NT and both Councill tip and Malecot catheters. They found that the Cope loop NT had better flow and stronger retention strength during *in vitro* testing compared to other devices [19]. Accidental removal is a preventable complication of all NT drains. All devices need an additional method to secure the device in place to prevent unintentional removal, such as a drain secure dressing or suture. An NT drain secure device is shown in Figure 36.2.

In the early years of PCNL surgery, it was common practice to use large and very large NT drains, sometimes only 2 Fr smaller than the tract [9]. It was thought that these large tubes would allow optimal drainage, and prevent urine leak and bleeding. However large-bore tubes also result in increased pain, and hence the use of smaller drainage tubes was explored [11, 12]. In almost

every report, small-bore NTs appeared to be superior in some aspects to large-bore drains. A prospective trial, a worldwide analysis of current PCNL practice, three randomized control trials, and a meta-analysis have confirmed this observation.

Maheshwari et al. undertook a study of PCNL in 40 consecutive patients, in which alternate patients were managed with a 28 Fr NT tube or a 9 Fr pigtail NT. They demonstrated that the small-bore NT was statistically associated with reduced postoperative pain, shortened duration of urinary leak, and a reduced period of hospital admission [20]. Similar findings were reported in four subsequent randomized trials. In these trials, a total of 211 patients were randomized to receive a large-bore NT or a small-bore NT. In all cases, the small-bore NT was assocated with less postoperative pain compared to the large-bore NT [14, 21–23].

Shen et al. performed an meta-analysis of large-bore NT versus small-bore NT. Nine studies, with a total of 547 patients, were included in their analysis. Post-PCNL drainage was differentiated into no NT tube, small-bore NT, middle-sized NT, and large NT. They concluded that no NT and small-bore NT were superior to middle and large-bore NT with regard to postoperative pian, analgesic requirements, and hospital stay [24], thus confirming the findings of the previous studies.

The Clinical Research Office of the Endourological Society (CROES) prospectively collected data from consecutive patients treated with PCNL over a 1-year period at 96 participating centers worldwide. Data were collected on 3968 patients. The goal of the study was to examine the postoperative outcomes and relate these to NT size. For this study, small-bore NT was considered to be ≤18 Fr and large-bore NT >18 Fr. They reported that large-bore NT had a significantly lower rate of hemoglobin reduction, overall complications, and a trend toward a lower rate of fever compared to small-bore NT. In addition, they found that large-bore NTs were statistically associated with a longer postoperative hospital stay [18]. All studies comparing large-bore to small-bore PCNL NTs are summarized in Table 36.1.

NUCs have been used in PCNL surgery as an alternative to large- and small-bore NTs. NUCs are similar to a NTs, but comprise a much longer tube and have a second curl at the distal end. The distal end is placed in the bladder or ileal conduit and the proximal end exits the nephrostomy tract. When tension is applied to the strings, a curl occurs at the tip to aid retention in the bladder or conduit. A second curl will occur more proximally to

**Table 36.1** Studies reporting larger bore nephrostomy compared to small-bore nephrostomy.

| Author | Year | *N* | Study type | Large bore | Small bore | Conclusions |
|---|---|---|---|---|---|---|
| Maheshwari [20] | 2000 | 40 | Prospective | 28 Fr NT | 9 Fr pigtail NT | Small-bore NT associated with reduced pain, reduced urinary leak, and reduced hospital stay |
| Pietrow [21] | 2003 | 30 | Randomized | 22 Fr Councill tip | 10 Fr pigtail NT | Small-bore NT associated with reduced pain |
| Desai [14] | 2004 | 30 | Randomized | 20 Fr NT | 9 Fr NT | Large-bore NT had most pain |
| Kim [22] | 2005 | 106 | Randomized | Malecot or 20 Fr NT | 8.5 Fr or 10 Fr NT | Small-bore NT provided greater patient comfort |
| De Sio [23] | 2011 | 45 | Randomized | 22 Fr NT | 12 Fr NT | Can safely be used instead of a large-size NT |
| Cormio L [18] | 2013 | 3968 | Consecutive | >18 Fr NT | ≤18 Fr NT | Large-bore NT associated with reduced bleeding and fewer overall complications |
| Shen [24] | 2012 | 547 | Meta-analysis | 16–24 Fr NT | None or 8–9 Fr NT | NT-free and small-bore NT similar |

*N*, total number of patients; NT, nephrostomy tube.

drain the renal pelvis. The NUC thus allows both internal and external drainage of urine. Canales et al. reported that a 6 Fr NUC minimized postoperative intravenous narcotic use, and expedited both recovery and discharge in 99 consecutive patients who underwent PCNL [25].

Kader et al. in a consecutive series of 30 patients reported that NUC use diminished postoperative pain while maintaining ureteral patency and nephrostomy access, and was also associated with decreased hospital stay [26]. In contrast, in a single-blind, prospective randomized trial of 188 patients, Weiland et al. compared an 8.3 Fr pigtail NT to an 8.2 Fr NUC and concluded that the pigtail NT resulted in greater ease of placement and less pain than the NUC drain [27]. This is not unexpected due to the size of the NUC and the difficulty in placing a device that requires both a distal curl and curl in the renal pelvis.

## Tubeless PCNL

Early PCNL innovators often performed "nephrostomy-free" surgery. In 1984, Wickham et al. published the results of 100 patients who underwent "nephrostomy-free" PCNL in which no internal or external drainage was used. They determined that nephrostomy-free PCNL was safe and associated with a shorter hospital stay than a PCNL with an external drain. Some patients in this study were discharged from hospital within 24 hours [8].

However, in 1986 Winfield reported that two patients developed serious complications due to premature removal of the NT after the extraction of simple upper-tract calculi. Both of these patients experienced significant hemorrhage requiring blood transfusion and urinary leakage requiring internal stenting. Both patients had a prolonged hospital admission [7]. Their conclusion was that NT drainage is unquestionably necessary in the early postoperative period to prevent such complications. This quickly became doctrine and consequently became the standard of practice for PCNL worldwide.

Over time it became evident that an NT was not absolutely necessary and hence the possibility of "nephrostomy-free" PCNL was revisited. However, it was 11 years after Winfield's report that Bellman et al. coined the phrase "tubeless PCNL." In their study of 50 consecutive patients, 30 patients were given JJ stents and Councill tip catheters (which were removed within 3 hours of surgery) and 20 patients received JJ stents only. These patients were compared to 50 age-, sex-, and procedure-matched patients who received an NT [17]. Bellman et al. found that the tubeless PCNL was a safe procedure, contrary to what was believed. In addition, they determined that the procedure offers various advantages over routine placement of an NT. These include reduced hospital stay, lower analgesia requirements, less postoperative pain, and quicker time to return to normal activities. In addition, a tubeless PCNL was shown to cost less than a standard PCNL with an NT.

Tubeless PCNL is shown in Figure 36.3.

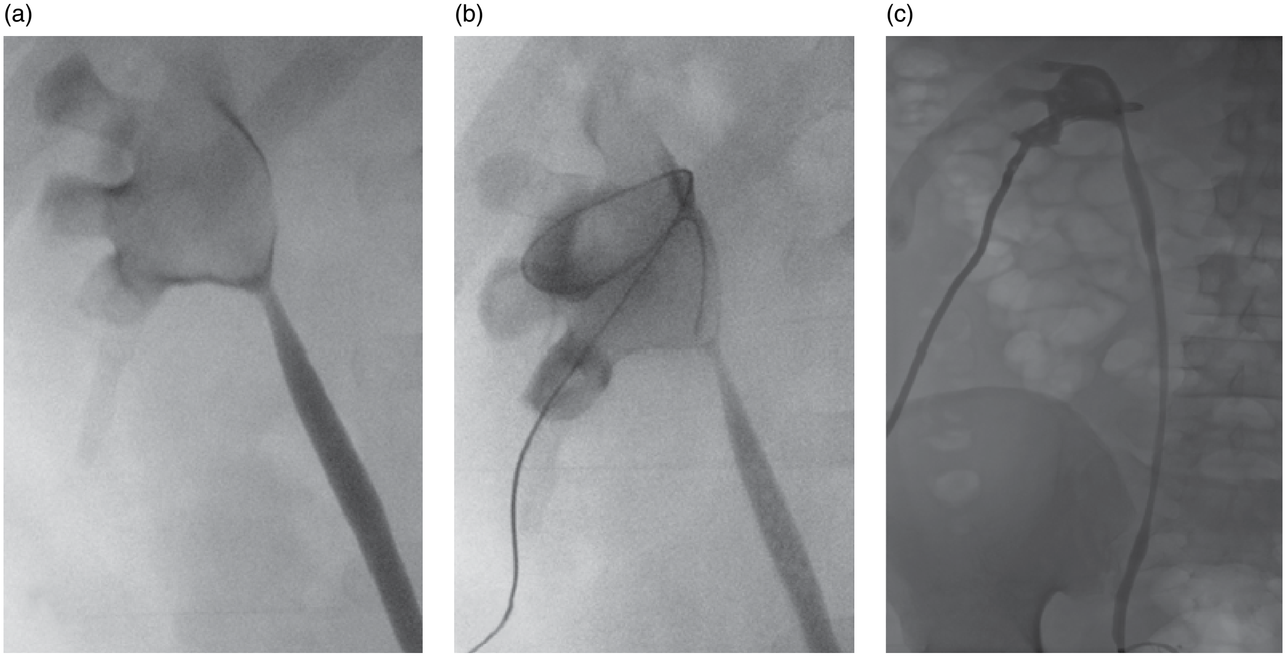

**Figure 36.3** Tubeless PCNL. (a) A large staghorn calculus. (b) Puncture was achieved through the lower pole calyx in supine position. (c) Antegrade placement of double-J stent for tubeless PCNL.

## Nephrostomy tube-free PCNL compared to standard PCNL with nephrostomy tube

Over the next two decades, 19 studies involving 1438 patients were published comparing NT-free PCNL to standard PCNL with NT placement. Sixteen of these studies compared NT placement to JJ stent, while three studies compared NT to externalized ureteric catheters. Nine of these studies evaluated the duration of hospital admission of NT-free PCNL compared to standard PCNL with an NT. Eight (88%) reported that NT-free PCNL led to shortened hospital admission [11, 12, 14, 15, 28–31]. Only one study (12%), a retrospective analysis found NT-free PCNL to be equivalent to standard PCNL with regard to hospital stay [32].

Eleven of these studies reported on postoperative pain and analgesic requirement, and nine (81%) trials showed that NT-free PCNL is associated with reduced postoperative pain and analgesia requirements compared to standard PCNL with NT placement [11–15, 28–30, 33]. Only two (18%) trials, found that postoperative pain and analgesia was equivalent between NT-free PCNL and cases with NT placement [31, 32]. Three trials specifically looked at urine leak and extravasation post-PCNL. Two trials reported that urine leak was less with NT-free PCNL [14, 33]. The other trial reported equal rates of urine leak for both NT-free and standard PCNL [32]. From these data, it can be concluded that NT-free PCNL is at least equivalent if not superior to standard PCNL with regard to admission duration, postoperative pain, and urine leak.

Since the original report by Bellman et al. many trials have compared the complication rates post tubeless PCNL and standard PCNL. Only six studies (31%), reported a higher rate of complications with tubeless PCNL [12, 31, 34–37]. The rate of complications in these studies ranged from 7.9% to 14% [35, 37]. However, this rate is well below a complication rate of 21.5% for PCNL, as reported in the CROES series [38]. It must be noted that the majority of these studies reported that tubeless PCNL is a safe procedure. Tubeless PCNL was found to be safe even in obese patients [36] and even if it is performed as an outpatient procedure [39]. Studies comparing tubeless PCNL to standard PCNL with an NT are summarized in Table 36.2.

Several authors have performed meta-analyses comparing tubeless to standard PCNL with an NT. First, Yuan et al. reported that tubeless PCNL was an effective and safe procedure for treatment of renal stones in selected patients. They concluded that tubeless PCNL was associated with a shorter hospital stay, less analgesic requirements, less urine leakage, and similar complication rates to standard PCNL [43]. Borges et al. reported that tubeless PCNL is a safe and effective procedure with a stone clearance rate comparable to that of standard PCNL. Tubeless PCNL was also associated with a shorter hospital stay and less postoperative urinary leakage. Pain reduction and reduction of analgesic requirements were also demonstrated [44].

Amer et al. found that the levels of pain recorded, analgesic requirements, duration of inpatient stay, and convalescence time were all significantly reduced in the tubeless PCNL [45]. Wang et al. found tubeless PCNL to be a good option in noncomplicated cases, with the advantages of reduced hospital stay and little need for postoperative analgesia [46]. Shen et al., in their meta-analysis, compared tubeless PCNL to small-bore NT, middle-sized NT, and large-bore NT. Similarly, they found tubeless PCNL and small-bore NT are similar in all measurements and possibly superior compared to middle- and large-bore NTs [24]. Overall, the meta-analyses showed that tubeless PCNL was significantly associated with less pain, leak, and shortened hospital stay. A summary of the meta-analysis findings is presented in Table 36.3.

## Tubeless PCNL compared to PCNL with a small-bore nephrostomy

Several studies have examined tubeless PCNL in comparison to small-bore NT placement. In three studies it was confirmed that tubeless PCNL was associated with reduced pain and shorter hospital admissions with similar rates of complications when in comparison to small-bore NT use [12, 14, 47]. This served to confirm the advantages of tubeless PCNL over standard PCNL with NT in select patients. The relevant data of these manuscripts are summarized in Table 36.4.

Small-bore nephrostomy is shown in Figure 36.4.

Patient selection is a key component for success with tubeless PCNL patients, as confirmed by numerous studies and meta-analyses [32, 41, 43, 46]. Patients ideally suitable for a tubeless PCNL should meet several criteria. These include:

- The planned surgery should be a straightforward and uncomplicated PCNL.
- Minimal bleeding must have been encountered.
- The calculus must be a noninfection stone.
- There should be absence of collecting system perforation.
- The urinary tract anatomy must be normal.
- Complete stone clearance should have been achieved.

If a patient has had any of the above potentially complicating factors then a tubeless procedure should be avoided. A tubeless PCNL decision-making aid is summarized in Table 36.5.

**Table 36.2** Studies comparing nephrostomy use and stent drainage.

| Author | Year | *N* | Study type | Drainage | Pain | Urine leak | Hospital stay | Complications |

An interval PCNL was carried out via the emergency nephrostomy tract and through a second tract. Two small-bore nephrostomies were placed at the end of the procedure.

## Tubeless PCNL Compared to Early Tube Removal

Some authors also have argued that the key disadvantage of a tubeless PCNL is that it eliminates the ability to do an interval nephroscopy for management of any residual stone fragments. Two studies have evaluated the results of removing a small-bore NT on the first postoperative day when stone clearance has been confirmed, and have compared this to tubeless PCNL [31, 48]. According to these small randomized studies of a total of 77 patients, early NT tube removal results in levels of analgesic

**Table 36.5** Patient selection factors for tubeless PCNL.

| Tubeless OK | Leave nephrostomy tube |
|---|---|
| Straightforward PCNL | Complicated PCNL |
| No bleeding | Significant bleeding |
| No infection | Infection |
| No collection system perforation | Collection system perforation |
| Normal urinary tract | Abnormal urinary tract |
| Compete clearance | Incomplete clearance |

requirement, decrease in hemoglobin, and hospital stay similar to those seen with tubeless PCNL. These data suggest that early NT removal is an equivalent option to tubeless PCNL, which also preserves the ability to do a repeat PCNL. Data relevant to this comparison are summarized in Table 36.6.

## Tubeless PCNL versus modifications to JJ stent placement

A potential downside to tubeless PCNL is the need for cystoscopy to remove the internal JJ stent, and also the potential for stent-related pain and symptoms. To avoid these difficulties, variations of tubeless PCNL have been examined and described. Choi et al. [49] and Yew and Bellman [13] reported tubeless PCNL with placement of a JJ stent with a distal tether exiting the urethra. This tether was then used to pull the stent out at the chosen time. Choi et al., in a randomized controlled trial of small-bore NT versus tubeless PCNL with the JJ stent tether exiting the urethra, noted that tubeless and small-bore NT cause similar postoperative discomfort, with indwelling stents appearing to quicken return to normal activities [49]. Yew and Bellman noted that using this technique pain scores were low and stent symptoms appeared minimal [13].

Unintentional removal of the JJ stent by the patient pulling on the tether has been reported as a disadvantage to this technique [49]. To prevent this, several studies have also examined JJ stent placement with a tether attached to the proximal end of the JJ stent and the tether exiting the nephrostomy tract [50, 51]. This allows the stent to be removed directly from the flank without the need for cystoscopy and reduces the risk of the patient inadvertently extracting the stent. This method also has the additional advantage of allowing for a second-look PCNL if needed, thus removing the key disadvantage of tubeless PCNL. The JJ stent can be pulled to the level of the skin and a guidewire may be placed through it and down the ureter to the bladder in order to re-establish access. In addition to these advantages, Shpall et al. found that utilization of the tether to remove the ureteral stent via the flank after tubeless PCNL is safe and a cost-effective improvement on the standard tubeless form of PCNL [50].

Externalized ureteric catheters have been used as alternatives to JJ stents. Several authors found such use of ureteric catheters to be safe, effective, economical, and associated with reduced analgesia requirements even in patients with moderate stone burden [37, 42, 52]. The obvious disadvantage of using a ureteric catheter is that it is difficult to keep this catheter in for a long period of time, thus negating the benefits of a tubeless procedure. Indeed, Mouracade et al. reported that 15 patients in their series required JJ stent placement after the removal of the ureteric catheter [52].

Nephrostomy and double-J stent placement are shown in Figure 36.5.

## Totally tubeless PCNL

Wickham et al. were the first to report totally tubeless PCNL, but termed it nephrostomy-free PCNL [8]. However, Winfield's unsuccessful trial of totally tubeless PCNL led to the practice being abandoned [7]. Nearly two decades passed before the totally tubeless technique was attempted again. Over the last decade, 14 different trials have re-examined totally tubeless PCNL and confirmed its place as a surgical option for endourologists [37, 53–65].

Three of these studies were retrospective, and they identified that totally tubeless PCNL had complication rates similar to those of PCNL with NT. These studies concluded that totally tubeless PCNL is a safe procedure and is associated with reduced hospital stay and analgesic requirements [54, 63, 64]. Only in one study did one

**Table 36.6** Studies comparing tubeless PCNL to PCNL with early tube removal.

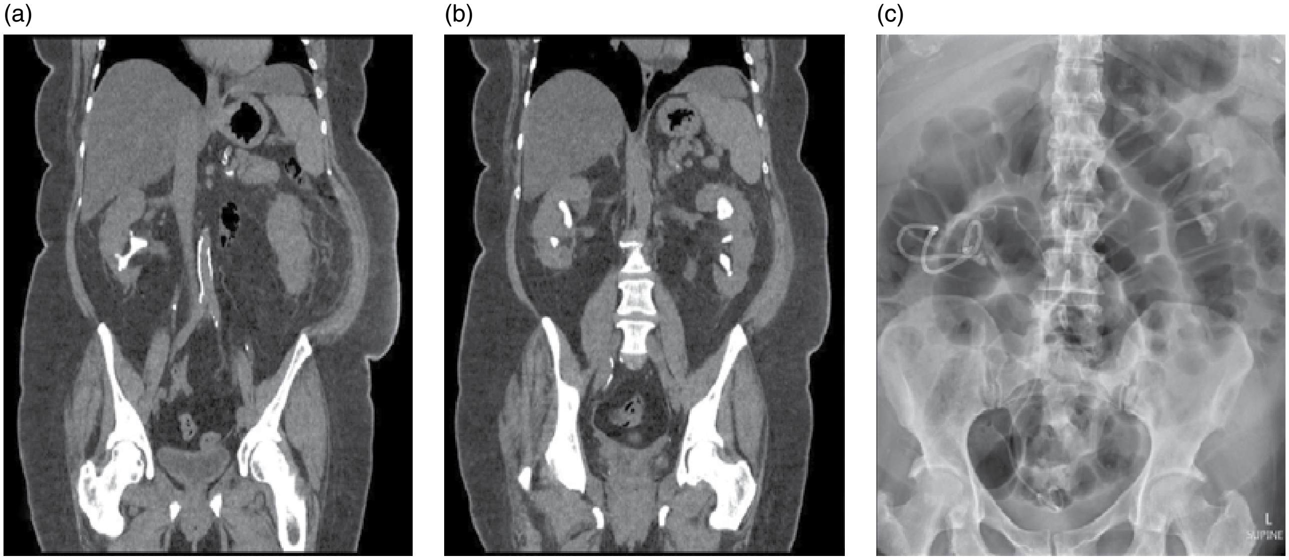

**Figure 36.5** Nephrostomy and double-J stent. (a, b) Bilateral staghorn stones. Right prone PCNL was performed. Complete stone clearance was achieved and a nephrostomy and double-J stent were placed for drainage. Nephrostomy was removed early within 24 hours. (c) The double-J stent was placed to allow for easy retrograde access for interval flexible ureteroscopy for further stone clearance.

patient require a JJ stent placement [54]. Three trials examined totally tubeless PCNL in selected patients only. These studies found totally tubeless PCNL to be safe, but associated with some complications. A sepsis rate of 5%, a major sepsis rate of 1% and a readmission rate of 1% was reported [55, 62].

Studies of consecutive patients who underwent totally tubeless PCNL again later demonstrated this procedure to be safe, and median hospital stays of 1.5–3.1 days were reported [37, 53, 65]. Five randomized control trials of totally tubeless PCNL and standard PCNL with NT have been reported. A total of 251 patients were included in these studies. All studies concluded that totally tubeless PCNL is a safe procedure, and is associated with reduced hospital stay and analgesic requirements in comparison to standard PCNL.

Furthermore, it has been reported that complication rates are similar for both totally tubeless PCNL and standard PCNL [56, 57, 59, 60]. Interestingly, Aghamir et al. reported that tubeless PCNL was even safe even in upper pole punctures [59]. Even more remarkably, Beiko et al. reported that totally tubeless PCNL could be performed as an outpatient procedure [58]. The trials reporting totally tubeless PCNL are summarized in Table 36.7.

## Hemostasis agents in tubeless PCNL tract

Several techniques have been tested to reduce the bleeding from the PCNL tract in tubeless and totally tubeless PCNL tracts. Techniques examined include diathermy of visible bleeding vessels, insertion of oxidized cellulose into the nephrostomy tract, use of fibrin sealant in the tract, putting gelatin sealant into the tract, and use of autologous fibrin glue. Jou et al. [66], Mouracade et al. [52], and Aron et al. [67] reported using diathermy to coagulate bleeding in intrarenal vessels and bleeding vessels in the tract [66, 67]. They found this procedure to be simple to do and safe as a hemostatic adjunct. However, these studies failed to prove any difference in bleeding complication rates between groups.

Aghamir et al. placed oxidized cellulose into the PCNL tract. They found that it did not decrease the complication rate and did not affect bleeding or urine leak rate [68]. Several authors have also examined the use of fibrin sealants in the PCNL tract [69–72]. Noller et al. [69] and Mikhail et al. [72] found fibrin sealants to be safe and feasible, while Gudeman et al. found it to be associated with shorter hospital stays and low complication rate [71]. However, the latter publication did report that two patients had bleeding complications and a further two patients had a urine leak with the use of the fibrin sealant [71].

Similarly, Shah et al. noted that fibrin sealant use is associated with less analgesic requirement and a shorter hospital stay [70]. The use of autologous fibrin glue in the PCNL tract was examined by Ziaee et al. [73]. In a randomized control trial they found that the use of such autologous fibrin glue had no effect on complication rate and that autologous fibrin glue played no significant role in improving results.

Gelatin matrix hemostatic sealant and thrombin-soaked absorptive gelatin sealants have also been used with some success in tubeless PCNL [40, 74, 75].

**Table 36.7** Studies evaluating totally tubeless PCNL.

| Author | Year | *N* | Study type | Pain | Urine leak | Hospital stay (days) | Complications | Observations |

**Table 36.8** Studies evaluating hemostatic agents in tubeless and totally tubeless PCNL.

| Author | Year | *N* | Study type | Hemostasis | Complications | Observations |
|---|---|---|---|---|---|---|
| Gudeman [71] | 2012 | 107 | Retrospective | Fibrin sealant | 2 patients bleeding, 1 patient had urine leak | Associated with shorter hospital stays, and lower complication rates |
| Noller [69] | 2004 | 8 | Consecutive | Fibrin sealant | Same | Tubeless PCNL using fibrin sealant appears to be safe and feasible |
| Shah [70] | 2006 | 70 | Consecutive | Fibrin sealant | Same | Fibrin glue was safe and was associated with less analgesic requirement and a shorter hospital stay |
| Mikhail [72] | 2003 | 43 | Retrospective | Fibrin sealant | Same | Fibrin glue is safe |
| Jou [66] | 2004 | 51 | Consecutive | Diathermy | Same | Cauterization of tract bleeding points may make this PCNL a more secure procedure |
| Aron [67] | 2004 | 40 | Consecutive | Diathermy | Same | Fulguration of visible intrarenal and tract bleeders is a simple procedure |
| Singh [40] | 2008 | 50 | Consecutive | Gelatin sealant | Same | Hospital stay, urinary extravasation, and analgesia were significantly lower |
| Nagele [74] | 2006 | 11 | Prospective | Gelatin sealant | Same | Closing the tract of the mini PCNL with gelatin matrix hemostatic sealant is a safe procedure |
| Lee [75] | 2004 | 2 | Prospective | Gelatin sealant | Same | May be of value in preventing bleeding after PCNL |
| Ziaee [73] | 2013 | 43 | Randomized | Autologous fibrin glue | Same | Autologous fibrin glue did not improve results |
| Aghamir [68] | 2006 | 22 | Randomized | Oxidized cellulose | Same | Did not affect bleeding or urine leak rate |

*N*, total number of patients.

Lee et al. found that gelatin sealant may be of value in preventing bleeding after PCNL [75]. Nagele et al. reported that closing the tract of the mini PCNL with gelatin matrix hemostatic sealant was a safe and complication-free adjunct to this procedure [74]. Singh et al. noted that hospital stay, urinary extravasation, and analgesia requirement were significantly lower with the use of a gelatin sealant [40]. Data concerning the use of hemostatic agents in PCNL are summarized in Table 36.8.

## Conclusion

The choice of postprocedure drainage after PCNL has been demonstrated to impact on the postoperative course of any patient undergoing this procedure. Small-bore NT usage has distinct advantages over large-bore NT with regard to postoperative pain and hospital stay. Patients without a NT after a PCNL have less pain, a shorter stay in hospital, use less analgesia, and are not at increased risk of bleeding complications or urine extravasation compared to those that receive an NT, particularly a large-bore NT. Similarly, totally tubeless PCNL has also been shown to be safe and effective in selected cases with outcomes similar to those in tubeless PCNL. In all instances of tubeless PCNL, however, the potential for a second-look PCNL via an established tract is unavailable.

It is clear that patient selection is critically important in consideration of suitability for a tubeless procedure to be undertaken. Any patients with infection stones, complex staghorn stones, an abnormal urinary tract, significant bleeding, or the need for a second-look procedure should have a small-bore NT placed at the end of the procedure. A JJ stent with the tether exiting the nephrostomy tract is an alternative option. For straightforward PCNL cases, a JJ stent may be placed and the PCNL can be simply closed with a suture or steri-strip. Hemostatic agents such as fibrin glue or gelatin-based agents may be placed in the tract to improve hemostasis if desired. If the surgeon wishes to remove the need for a cystoscopy to remove the JJ stent, the tether can be left in place, exiting the urethra so that the stent can be removed easily once stone-free status has been confirmed. In all instances consideration of the individual circumstances of the patient and their stone burden is required to guide the endourologist to the optimal exit strategy after PCNL.

# Problems with Residual Stones

*Noah E. Canvasser & Margaret S. Pearle*

*Department of Urology, University of Texas Southwestern Medical Center, Dallas, TX, USA*

## Introduction

Recent epidemiologic studies show that the prevalence of nephrolithiasis is rising. In the United States, nearly 9% of the population will be diagnosed with a stone in their lifetime [1], with comparable increases in prevalence seen in European and Asian countries [2]. Accordingly, cost estimates for the diagnosis and treatment of stone disease in the United States are projected to increase substantially, from US$3.79 billion/year in 2007 to US$5.03 billion/year in 2030 [3]. Because of this, efforts to improve the efficiency of stone care are imperative.

Although nearly all patients with stones requiring treatment are now managed initially by noninvasive or minimally invasive means, and open surgery has all but disappeared [4], the need for secondary procedures to remove persistent stones or residual fragments (RFs) has increased. In this chapter, we review the outcomes of patients left with RFs after minimally invasive stone interventions, including shock-wave lithotripsy (SWL), ureteroscopy (URS), and percutaneous nephrolithotomy (PCNL).

## Shock-wave Lithotripsy

Although the introduction of SWL in 1980 by Chaussy et al. revolutionized the management of stone disease [5], it also brought with it a new management challenge – what to do with fragmented stones that fail to pass spontaneously. Although early reports documented high SWL treatment success rates, 20–30% of patients were left with ≤4–5 mm RFs [6, 7]. The term “clinically insignificant residual fragments” (CIRFs) was coined to denote small fragments that were expected to ultimately pass spontaneously and were considered a benign consequence of stone fragmentation. Indeed, Moon and Kim reported stone-free rates (SFRs) of 33%, 73%, and 93% at 1, 3, and 6 months, based on kidney–ureter–bladder (KUB) radiographs post-SWL among 248 patients with small RFs, validating the assumption that most small fragments eventually pass [8]. These authors concluded that practitioners should wait six months after SWL before offering repeat or secondary treatment.

Buchholz and associates also found a high rate of fragment clearance after SWL [9]. Among 55 patients with <5 mm RFs, 88% were stone free at a mean of 2.5 years after SWL. Likewise, Osman et al. found that 79% of 173 patients with ≤4 mm RFs after SWL cleared their RF within six months of SWL [10]. However, other studies have been less optimistic about fragment clearance. El-Nahas et al. used computed tomography (CT) to follow 154 patients left with ≤5 mm RFs at over three months after SWL and found that only 13% of patients had cleared their fragments at a mean of 31 months [11].

Streem et al. were the first to recognize that not all small RFs after SWL remain inert [12]. They identified 160 patients treated with SWL who were left with ≤4 mm RFs and found that 43% experienced a symptomatic event and/or required surgical intervention at a mean of 26 months following treatment. By Kaplan–Meier analysis, the 5-year probability of becoming symptomatic or requiring surgery was 71% and the probability of stone growth was 20%, indicating that RFs can have significant consequences.

Since the report by Streem et al., other investigators have likewise reported on the natural history of RFs after SWL and found that they can be a significant source of morbidity. Khaitan et al. prospectively followed

*Smith’s Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

75 patients with ≤4 mm RFs identified on abdominal radiographs obtained three months after SWL and found that at a mean follow-up of 15 months, 24% of patients cleared their fragments. However, among the 57 patients who retained their RFs, 72% demonstrated growth of the fragments, 61% experienced pain, and 42% required surgical intervention [13]. Osman et al. reviewed a series of 173 patients with RFs post-SWL and found that 21.4% of patients in whom there was growth of the fragments required surgical intervention at a mean of 4.9 years [10]. El-Nahas et al. followed 154 patients with RFs for a mean of 31 months, and noted that nearly half (48.7%) required surgical intervention or needed pain medication due to progression or movement of the RFs [11]. Finally, Candau et al. reviewed 83 patients with ≤4 mm RFs identified on three-month post-SWL imaging and found that at a medium follow-up of 40.6 months, 37% of patients demonstrated an increase in stone size by nephrotomogram imaging, and 58% of those patients underwent secondary treatment [14].

In contrast, Buchholz et al. followed 44 patients with ≤5 mm RFs after SWL for a mean of 33 months and found that only 12.5% of patients retained those fragments at the end of the period of observation and no patients experienced pain with stone passage [9]. Furthermore, only 2.1% of patients showed an increase in stone size.

Factors associated with an adverse outcome as a consequence of small RFs has been investigated. Although Candau et al. failed to identify any variables associated with clinically significant outcomes [14], other investigators reported that larger fragment size and/or greater stone burden correlated with worse outcomes [10, 11, 13]. In addition, RF location likely plays a role, as renal pelvic fragments tend to pass spontaneously [13], whereas calyceal, particularly lower pole, stones have lower clearance rates [10, 13]. Sahin et al. identified 80 patients with RFs after SWL and divided them into those with ≤2 mm (*n* = 30), 2– ≤ 4 mm RFs (*n* = 21), and >4 mm RFs (*n* = 35) [15]. Fragment clearance occurred in 100% of patients with ≤2 mm RFs, 76% of patients with 2– ≤ 4 mm RFs and 52% of patients with >4 mm RFs within three months. Moreover, emergency department (ED) visits were required in 19% and 51% of patients with 2– ≤ 4 mm and >4 mm RFs, respectively, compared to no ED visits in patients with ≤2 mm RFs. Accordingly, quality of life assessment using the SF-36 survey demonstrated that larger RF size was associated with significantly lower scores at one month and three months following SWL.

Considering the totality of these studies, growth of RFs after SWL occurred in 29% of patients, 25% of patients became symptomatic as a result of their RFs, and 33% of patients with RFs required intervention (Table 37.1). However, there are several limitations in comparing these natural history studies. Differences in imaging modalities result in differences in the sensitivity of detecting RFs. Furthermore, the definition of small RF after SWL is variable and has included ≤4 mm [12–14] and ≤5 mm [9–11]. Regardless, the literature has been reasonably consistent in identifying adverse outcomes in more than a quarter of patients with RFs after SWL.

## Ureteroscopy

Historically, series of URS for intrarenal calculi have demonstrated high SFR, ranging from 77 to 91% [16–18]. With further improvement in URS technology, progressively larger renal calculi have been addressed, with reported SFRs of approximately 85% in series of patients with >2 cm stones [19, 20]. However, these early URS series relied on abdominal radiography and/or ultrasonography to assess stone-free status, imaging modalities known to be inferior to CT for detecting RFs. Furthermore, the fate of RFs after URS was not typically assessed.

In a multicenter randomized controlled trial (RCT) comparing URS and SWL for the treatment of patients with ≤1 cm lower pole stones, Pearle et al. used three-month CT to determine SFRs and found sobering outcomes for both modalities: 35% for SWL and 50% for URS [21]. More contemporary series have likewise validated lower SFRs for URS than previously reported. Portis et al. prospectively evaluated 69 patients undergoing URS for 5–15 mm renal or proximal ureteral calculi who were imaged with CT one month post procedure [22]. Among 58 patients who completed follow-up, the mean CT SFR was 53.6%. Furthermore, at mean follow-up of 1.4 years, 5.2% of patients underwent repeat endoscopic intervention. Macejko et al. reviewed 92 patients who underwent 119 ureteroscopic procedures for renal or ureteral calculi and reported an SFR by CT of 50.4% [23]. When stratified by stone location, the SFR for stones in the kidney only was 34.8% compared with 80% for stones located in the ureter only. Rippel et al. also reviewed 265 URS procedures among 248 patients who were imaged with CT postoperatively and found an SFR of 62% [24]. On multivariate analysis, they determined that only pretreatment stone diameters of 6–10 mm (OR 2.03, 95% confidence interval (CI) 1.07–3.84, $P = 0.03$) and >10 mm (OR 3.74, 95% CI 1.57–8.94) were independent predictors of RFs.

The low SFR after URS revealed by CT in these studies underscores the need to understand the fate of these RFs. Several investigators have evaluated the natural history of RFs after URS. Rebuck et al. reviewed 330 URS procedures among 307 patients and identified 46 patients with 51 renal units containing ≤4 mm RFs [25]. Restricting

their analysis to only those with calcium-based stones, these investigators determined the outcome of these patients out to a mean follow-up of 18.9 months. They found that 22% of patients passed their fragments, 59% remained asymptomatic with retained fragments, and 20% experienced a stone-related event (SRE) (ED visit, hospitalization, or intervention) at a mean of 27 months post operatively. In addition, they noted that asymptomatic stones tended to demonstrate minimal growth (from 2.7 mm at three months to 3.0 mm at 33 months), while patients who experienced an SRE demonstrated growth of RFs from 2.5 mm at three months to 6.3 mm at 27 months, suggesting perhaps that stone growth portends increased risk of an SRE.

Ozgor et al. also followed 44 patients with ≤5 mm RFs detected on CT within three months of URS with annual CT imaging [26]. At a mean of 30.5 months follow-up, 66% of patients either passed their RFs or remained asymptomatic with no stone progression. However, stone growth was detected in 11% of patients, 23% experienced symptoms, and surgical intervention was required in 25%.

Portis et al. used need for repeat surgery as the primary outcome parameter in a retrospective review of 226 URS procedures in 217 patients for one or more renal or ureteral calculi for which no individual stone exceeded 15 mm in size [27]. SFR (by CT in 71% of renal units) at one month following stent removal was 53%. At a median follow-up of 4.1 years, 8.7% of patients ($n = 19$) underwent repeat surgery, including 14 URS and 5 PCNL procedures. By Kaplan–Meier analysis, the repeat surgery rate at 1 and 5 years was 5.8% (95% CI 3.4–9.8) and 8.6% (95% CI 5.6–13.1), respectively. The need for repeat surgery correlated strongly with the size of the RF ($P < 0.001$). When outcomes were stratified by RF size, need for repeat surgery at 1 and 5 years was 2.3% and 3.5%, respectively, for patients with no RFs; 20.8% at both 1 and 5 years for patients with RFs of >2– ≤ 4 mm; and 30.1% and 46.2%, respectively, for patients with RFs of >4 mm. For patients with ≤2 mm RFs, 1- and 5-year cumulative repeat surgery rates were low at 1.6% and 2.5%, respectively, but higher at 8.5% at both 1 and 5 years for patients with ≤4 mm RFs. Consequently, although patients with RFs ≤2 mm in size rarely required repeat surgery, those with RFs >2 mm were at substantially greater risk.

The largest series to date evaluating the fate of small RFs after URS is a multicenter retrospective review from Chew et al., representing the Endourology Disease Group for Excellence (EDGE) consortium [28]. This group identified 232 patients who underwent URS at one of six centers and were left with RFs of any size. At a mean follow-up of 16.8 months, 44% of patients experienced an SRE, defined as stone growth, stone passage, need for reintervention, or complication, and 29% underwent surgical intervention. When outcomes were stratified by RF size, they found that stone passage rates were comparable between those with RFs ≤4 mm and those with RFs >4 mm (26–27%). However, larger fragments were more likely than smaller fragments to demonstrate stone growth (59% vs. 28%, respectively, $P < 0.001$), to require intervention (38% vs. 18%, respectively, $P = 0.01$) and to be associated with complications (59% vs. 22%, respectively, $P = 0.039$).

Overall, taking into account three natural history series comprising 322 patients, 38% of patients experienced pain or an SRE and 26% of patients required surgical intervention (Table 37.2). Multivariable analyses have demonstrated that stone growth and the occurrence of symptomatic events after URS are associated with non-lower pole calyceal location [25], preoperative stone burden [24, 26] and hypocitraturia [26].

The increasing evidence of adverse outcomes associated with RF after URS has coincided with a contemporary debate over URS technique, namely “dusting” versus “basket extraction.” While “dusting” represents “complete” stone fragmentation to allow spontaneous passage of fragments over time, “basket extraction” implies an active retrieval process aimed at leaving the patient stone free at the end of the procedure. The EDGE consortium prospectively evaluated patients undergoing URS with either a “dusting” or “basketing” strategy and found a higher SFR by KUB/ultrasound in the “basket extraction” group than in the “dusting” group (86% vs. 59%), without any difference in readmission, reintervention, or symptomatic events at three-month follow-up [29]. Of note, the short follow-up currently limits any meaningful conclusions regarding the ultimate fate of RFs after URS, but longer prospective follow-up from this trial should ultimately add evidence to the RF debate.

## Percutaneous nephrolithotomy

Among the minimally invasive procedures for stone removal, PCNL is the most efficacious modality and the one that is typically used to treat large and/or complex renal calculi. Multi-institutional reporting through the Clinical Research Office of the Endourological Society (CROES) has demonstrated an overall SFR for PCNL of 76% [30]. However, with only 14% of these results based on CT imaging, SFRs are likely underestimated and RFs after PCNL are likely more prevalent than previously thought. Indeed, Pearle et al. prospectively evaluated 36 patients/41 renal units undergoing PCNL for >3 cm renal calculi who were imaged with CT on postoperative day 1 and identified RFs in 80.5% of renal units despite careful

flexible nephroscopy at the time of initial PCNL [31]. With second-look flexible nephroscopy (SLFN), however, an SFR of 90% was ultimately achieved. Osman et al. also prospectively evaluated 98 patients/100 renal units who were imaged with CT within 48 hours post PCNL and found RFs in 62% of patients [32]. These studies underscore the high prevalence of RFs after initial PCNL and highlight the potential for long-term sequelae if CT is not utilized to assess stone-free status and secondary flexible nephroscopy is not performed when RFs are detected. Table 37.3 lists clinically relevant series reporting outcomes of RF after PCNL.

Several investigators reviewed their series of PCNL to determine the outcomes of patients with RFs. Raman et al. reviewed 527 patients who underwent PCNL and identified 42 patients with RFs (median size 2 mm) who were observed for a minimum of six months [33]. At a mean follow-up of 32 months, 43% of patients experienced an SRE (defined as stone growth or need for ED visit and/or hospital admission) and 61% of those patients (26% overall) required surgical intervention. Multivariate logistic regression analysis revealed that maximum RF size >2 mm (HR 3.9, 95% CI 1.3–11.5, $P = 0.01$) and location in the renal pelvis or ureter (HR 4.4, 95% CI 1.0–13.5, $P = 0.01$) were independent predictors of an SRE. On Kaplan–Meier analysis, 1- and 3-year probability of freedom from an SRE was 87% and 65%, respectively, for RFs ≤2 mm and 56% and 33%, respectively, for RFs >2 mm in size.

Ganpule et al. identified 187 patients with RFs after PCNL (mean RF size 38.6 $\text{mm}^2$) and found that 45% of RFs passed spontaneously, most within three months [34]. No RF >100 $\text{mm}^2$ cleared without intervention, and RF size correlated inversely with spontaneous passage rates. On the other hand, Altunrende et al. found that among 38 patients with ≤4 mm RFs after PCNL and a minimum follow-up of 24 months (mean 28.4 months), only 8% spontaneously passed their fragments [35]. Additionally, although no patient required surgical intervention, 26% experienced symptoms (pain or hematuria), and 21% demonstrated growth of the RFs.

Osman et al. also reviewed the outcomes of 75 patients with ≤5 mm RFs after PCNL (mean RF size 4.7 mm) [36]. At a mean follow-up of 36 months, a third of patients had apparently passed their RFs spontaneously (presumably asymptomatically), 29% retained stable, asymptomatic RFs, a third demonstrated growth of the RFs, and 4% had an RF pass into the ureter. All of the 25 patients demonstrating growth of RFs and the three patients presenting with ureteral stones underwent surgical intervention. On multivariate analysis, only RF size >3 mm correlated with stone growth or symptomatic passage into the ureter (OR 1.882, 95% CI 0.919–3.854, $P = 0.05$).

Olvera-Posada et al. identified 44 patients with RFs (median size 5.5 mm) among 202 patients who underwent CT imaging post PCNL and had at least 12 months of follow-up [37]. At a mean follow-up of 57.9 months, 45.5% of patients remained asymptomatic while 54.5% of patients became symptomatic (pain or UTI) and 72.7% of patients underwent surgical intervention (electively or urgently). Overall, 84% of patients demonstrated growth of RFs at last follow-up. By Kaplan–Meier analysis, the 1- and 5-year probability of remaining intervention-free with the RFs was 91% and 29%, respectively. Furthermore, the likelihood of requiring intervention was significantly greater in patients with RFs >4 mm compared to those with RFs ≤4 mm. Of note, the likelihood of a symptomatic event was unrelated to RF size.

Predictors of an SRE in multivariable models included RF size >2 mm [33], >3 mm [36], >4 mm [37], stone location in the renal pelvis [33] or ureter [33], or no associated factors [37]. Larger stone size has consistently been shown to predict need for retreatment [33, 37, 38], but stone composition (notably struvite/apatite) may additionally correlate [37, 38]. Raman et al. showed that patients with RFs >2 mm had a 53% retreatment rate compared to 8% in those with RFs ≤2 mm [33]. In the longest follow-up study evaluating retreatment after PCNL, Portis et al. reviewed 150 patients undergoing 160 PCNL procedures to determine need for repeat surgical intervention [38]. At a median follow-up of 5.4 years, after controlling for stone composition, renal units with RFs were found to be 7.87 times more likely to require retreatment than those rendered stone free (95% CI 2.21–28.0, $P = 0.001$). By Kaplan–Meier survival analysis, cumulative retreatment rates at 7 years were 4.1% in those with no RF (95% CI 0–8.7), 33.3% in those with RF ≤4 mm (95% CI 6.1–60.5) and 29.8% in those with RF >4 mm (95% CI 12.1–47.5). Furthermore, non-calcium-containing RFs had a greater likelihood of requiring retreatment compared to calcium-containing RFs (56% vs. 23%, respectively).

Overall, among these series, stone growth occurred in 45%, symptoms developed in 42%, and surgical intervention was needed in 43% of patients (Table 37.3). Because of this, there is compelling evidence to support SLFN after PCNL to retrieve RFs. However, SLFN is costly and associated with additional morbidity, hospital length of stay, and cost. Raman et al. performed a cost effectiveness analysis to compare the cost of SLFN with the cost of expectant management in patients with RFs, taking into account the cost of the additional procedure and hospital length of stay for SLNF and the cost of additional ED visits and need for retreatment arising from observation of RFs [39]. Based on rates of RFs and need for surgical intervention obtained from the literature, the cost of observing RFs ≤4 mm was estimated at US$1743

RF, residual fragment; IQR, interquartile range.

and the cost of observing RFs >4 mm was US$4674. With a cost of SLFN in 2009 of US$2475, the model predicted that SLFN was cost-advantageous for RFs >4 mm, not cost-beneficial for ≤2 mm RFs, and only marginally cost-advantageous for RFs 3–4 mm in size [39]. Therefore, using the outcomes defined by prior work, SLFN should be strongly considered when RFs >2 mm remain after PCNL.

## Residual fragments in the pediatric population

Few studies have evaluated the outcomes of RFs after minimally invasive and noninvasive stone procedures in children. With evidence suggesting a growing prevalence of nephrolithiasis in children [40] and the longer time period of observation in this population, knowledge of the potential adverse effects of RFs is all the more important when selecting a treatment modality.

In the only series to evaluate the outcomes of RFs after SWL in children, Afshar et al. reviewed 26 children (mean age 7 years) with ≤5 mm RFs followed for a mean of 46 months [41]. Only 15% of RFs passed spontaneously, while 35% of patients experienced a symptomatic episode and 35% demonstrated stone growth. Of note, the only significant predictors of adverse outcomes in this population were the presence of a metabolic disorder and growth of RFs.

Dincel et al. reviewed the outcomes of 85 children (mean age 9 years) with ≤4 mm RFs after PCNL and found a rate of spontaneous passage of 26%, growth of RFs in 21%, and need for secondary intervention in 29% of patients at a mean follow-up of 22 months [42]. Likewise, El-Assmy et al. identified 61 children (mean age 6 years) with RFs (median size 4 mm, range 2–5 mm) after PCNL who had a mean follow-up of 18 months, and found comparable rates of spontaneous passage (26%), stone growth (25%), and need for intervention (23%) [43]. The only predictor of reintervention in this series was a history of stone disease.

## Medical therapy

Historically, dissolution therapy, particularly for stones composed of struvite and uric acid, was utilized after open stone surgery if RFs remained [44, 45]. With technological advances in endoscopic management of stones and better patient selection for SWL, such interventions are now only of historical interest. However, *in vitro* studies have demonstrated that even normal urine parameters can induce growth of RFs after intervention [46], and inhibitors of crystallization, such as phytate and citrate, can impede this process [47, 48]. Because of this, the ability to medically manage RFs after intervention is a promising area of study.

Cicerello et al. investigated the use of potassium citrate in patients with <5 mm sterile calcium or struvite RFs after SWL. Among 70 patients randomized to receive either alkali citrate or placebo, the authors found that citrate therapy significantly increased 12-month stone clearance rates over placebo (74% vs. 32% clearance, respectively, for sterile calcium stones and 86% vs. 40% clearance, respectively, for infection stones) and decreased stone growth [49]. Fine et al. also found that targeted medical therapy improved stone clearance in patients with RFs after SWL. At a mean follow-up of 36 months, the remission rate in 36 patients treated medically was significantly higher than in 13 patients not on medical therapy (63.9% vs. 23.1%, $P < 0.05$) [50]. In a similar retrospective study after PCNL, Kang et al. reviewed 40 patients with RFs and found a significantly higher remission rate (77% vs. 21%, respectively) and a lower stone formation rate (0.02 vs. 1.0 stones/patient/year) in patients treated with medical therapy compared with those on no medical therapy [51].

Soygur et al. investigated the role of potassium citrate therapy in promoting clearance of RFs after SWL [52]. Among 34 calcium oxalate stone formers with <5 mm RFs four weeks after SWL randomized to potassium citrate or placebo, stone remission rates at 12 months were higher in the potassium citrate group (44.5%) than in the placebo group (12.5%). Likewise, Lojanapiwat et al. randomized 76 patients who underwent SWL or PCNL to potassium–sodium citrate or placebo [53]. At 12 months follow-up, among the 37 patients who had <4 mm RFs, 30.8% of patients on potassium–sodium citrate compared to 9.1% on placebo were stone-free (RR 1.38, 95% CI 0.96–1.98). Furthermore, the RFs increased in size or new stones recurred in 54.5% of patients in the control group versus 7.7% of patients in the potassium–sodium citrate group (RR 0.3, 95% CI 0.08–1.0).

Other investigators assessed the role of hydrochlorothiazide, a known hypocalciuric agent, in promoting fragment clearance or reducing stone growth. Arrabal-Martin et al. randomized 100 patients with RF after SWL to hydrochlorothiazide or placebo [54]. At a mean follow-up of 36 months, overall fragment expulsion was higher in the hydrochlorothiazide group than in the placebo group (72 vs. 36%), even in the setting of a higher rate of secondary SWL in the placebo group (42 vs. 18%, respectively). Additionally, 58% of RFs in the placebo arm demonstrated stone growth compared to only 18% in the hydrochlorothiazide arm. In a subset of patients with hypercalciuria, the differences were even more pronounced.

These studies highlight the potential benefit of adjunctive medical therapy in promoting clearance and reducing the growth rate of RFs. Unfortunately, medical therapy cannot prevent the symptoms or the unpredictability associated with passage of these fragments.

## Conclusion

An abundance of literature suggests that regardless of the modality, RFs can be problematic after any surgical intervention. The likelihood of adverse outcomes seems to correlate with stone size, although the optimal size cutpoint for safe observation of RFs after surgery is unclear but likely lies somewhere around 2 mm. Because of this, the goal for every stone procedure should be to maximize stone clearance so as to limit regrowth, symptomatic events, and need for unplanned secondary intervention, all of which are associated with significant cost and decrement in quality of life. In patients with metabolic derangements or infectious etiologies, this recommendation is potentially even more important, and adjunct medical therapies should be considered.

## Introduction

The ureters are muscular tubes located in the retroperitoneum that deliver urine from the bilateral kidneys to the urinary bladder in the pelvis. They originate as extensions of the renal pelvis and average 22–30 cm in length and 1.5–6.0 mm in diameter in adults [1]. They are divided by convention into three sections: proximal, middle, and distal (Figure 38.1). Alternatively, they can be divided into abdominal, pelvic, and intramural portions. The proximal ureter begins at the renal pelvis at about L2 and ends at the level of the proximal sacrum. The middle ureter refers to the ureter from the proximal sacrum to the distal edge of the sacrum. The distal ureter is the portion of the ureter that runs from the distal edge of the sacrum and ends at the ureteral orifice.

## Embryology

During fetal development, three urinary systems with increasing complexity and function appear: the pronephros, the mesonephros, and the metanephros. The pronephros is a rudimentary group of cells with limited excretory function that appears in the cervical region during the fourth week of development which completely regresses by the end of that week [2, 3]. During the fourth week as the pronephros begins to regress, the mesonephros, which is derived from intermediate mesoderm, appears bilaterally on either side of what will be the spine [4]. The developing gonadal structures are just medial to the mesonephros, and the two developing organs together make up the urogenital ridge. At this point, further development of the mesonephros results in formation of the excretory tubules, capillaries, glomeruli, and Bowman's capsule. A collecting system called the wolffian or mesonephric duct also forms. However, the mesonephros regresses like the pronephros.

The definitive urinary system is not formed until the permanent kidneys develop from the metanephric mesoderm in the fifth week [5]. The ureters and collecting system are derived from the ureteric bud, which grows from the wolffian duct. The wolffian duct otherwise regresses; however, in males, its remnants also contribute to structures of the genital system. Molecular signaling between the abutting ureteric bud and metanephric tissue results in development of the collecting system from the ureteric bud, specifically, the ureters, renal pelvis, calyces, and collecting tubules. The metanephric tissues become the glomeruli and nephrons.

At around 18 days, the ureter undergoes elongation, which results in redundancy and the formation of pleats that straighten as the ureter continues its elongation. As the ureter elongates it loses its lumen in the mid portion during days 37–40. Recanalization originates in the mid portion and extends cephalad and caudal to the ureteropelvic junction and ureterovesical junction, respectively. Hydrostatic pressure of secreted urine from the mesonephros is thought to contribute to recanalization. At nine weeks of development the metanephros, which will become the mature kidney, starts to produce urine. As this fetal urine drains into the bladder, patency of the ureter is maintained.

## Anatomical course

The gentle sigmoid curve that the ureters take begins at the ureteropelvic junction (UPJ). They begin posterior to the renal vessels close to the renal hilum, lateral to the transverse processes of the lumbar vertebrae. The right ureter starts posterior to the second part of the duodenum

and descends posterior to the ascending colon, cecum, appendix, and terminal ileum [1, 6]. The branches of the superior mesenteric artery and vein lie anterior to the right ureter. Both ureters lie just anterior to the psoas muscles, pass over the genitofemoral nerve, and under the gonadal vessels. The left ureter is attached to the mesocolon and passes under the sigmoid colon and its vessels, and travels behind the intersigmoid fossa. The left ureter also passes behind the inferior mesenteric artery in close proximity. The peritoneum covers the ureters anteriorly until they enter the pelvis.

As the ureters enter the pelvis, they also travel across the common iliac vessels and its branches. At the level of the ischial spine, the ureters lose their peritoneal layer and become completely retroperitoneal. The ureters further descend medially toward the bladder and pass anteriorly to the obturator neurovascular structures and posterior to the obliterated umbilical artery. In the male, the ureters pass behind the ductus deferens. In the female, the ureters pass under the ovarian and uterine vessels. In both genders, the ureters enter the bladder wall at an oblique angle at the ureterovesical junction (UVJ).

The caliber of the ureteral lumen varies along its course with average ranging from 1.8 to 3.0 mm [7]. There are three main areas of anatomical narrowing important during endoscopic procedures: at the UPJ, at the pelvic brim at the iliac vessels, and at the UVJ, with the UVJ being the narrowest of the three.

## Histology

The ureter can be separated into three histologic layers: mucosal layer, muscular layer, and adventitial layer. The innermost layer in the mucosa begins with the urothelium (transitional epithelium), which lines the lumen and is atop the lamina propria. The lumen of the decompressed ureter has a stellate (Figure 38.2) configuration that becomes progressively circular as it becomes distended with urine during peristalsis [8]. The lamina propria, composed of collagen fibers and fibrocytes, houses the microscopic vascular supply of the wall of the ureter and unmyelinated nerves. The muscular layer carries bundles of smooth muscle fibers that control peristalsis. These bundles of muscles are arranged longitudinally into subtle layers. The prominence of each muscle layer depends on the segment of ureter. In the abdomen the muscle layers are extremely thin and almost nonexistent on light microscopy [9]. In the pelvis, two layers of muscles have been identified:

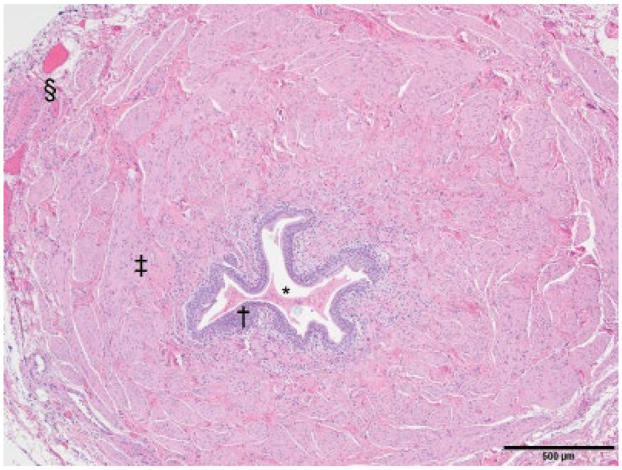

**Figure 38.2** Cross section of ureter under light microscopy demonstrating the lumen (*), mucosal layer (†), muscular layer (‡), and adventitial layer (§).

the outer circular layer and an inner longitudinal layer [10]. Additionally, as the ureter enters the bladder, the inner longitudinal layer becomes even more prominent and is thought to eventually contribute to the muscles fibers in the floor of the bladder to form the trigone. The adventitial layer, also called the ureteric sheath, carries two vascular networks that supply the ureteric wall. The inner network has perforating arteries that are continuous with the vascular network of the mucosal layer. The outer network contains vessels that run longitudinally along the course of the ureter. The adventitial layers also consist of collagen, fibrocytes, nerves, and muscle cells. All three layers contain unmyelinated nerve fibers.

## Blood supply

Vascular supply to the ureters varies along its course. It relies on an anastomotic network of vessels in the adventitia, which is the richest in the proximal and distal segments. Although the vast majority of the blood supply to the ureters is provided by the abdominal aorta, renal, gonadal, common iliac, and internal iliac arteries, there is considerable variation to the contribution of vessels of origin for the remaining blood supply [11]. The upper third of the ureter is supplied mostly by branches of the renal artery with contributions from the gonadal and colic arteries. The vascularization of the mid third of the ureter is variable, with contributions from the aorta, iliac, and gonadal arteries. In some patients the mid ureter is supplied primarily by peritoneal vessels. The distal ureter receives its main arterial supply from the internal iliac, superior vesical, and inferior vesical artery. Additional ureteral vascular supply may be provided by branches from the renal capsular arteries, adrenal arteries, umbilical artery, aortic branches, uterine artery, and the middle rectal artery. These small arterial branches, which may be quite long in relation to their caliber, subdivide in ascending and descending branches and coalesce into the periureteric arterial plexus within the adventitia. The supplying dominant branches enter the ureter differently at various segments. In the abdomen, arterial branches supplying the ureter enter anteriorly and medially. In the pelvis, the arterial supply enters posteriorly and laterally. This is important when considering incisions into the ureter if ischemia and development of strictures are to be avoided.

The venous drainage of the ureters begins in the lamina propria and extends into the adventitia. This venous plexus drains proximally via the renal and gonadal veins and distally into the vesical venous plexus and uterine veins in females and gonadal veins.

## Lymphatics

Lymphatic drainage of the ureter is dependent on the ureteral segment. The proximal ureter is drained by the ipsilateral renal lymphatics. In other words, they are drained by the aortic lymph nodes surrounding the gonadal artery. The middle ureter on the right is drained by the right paracaval and interaortocaval lymph nodes. The left middle ureter is drained by the left paraaortic lymph nodes. The pelvic ureters bilaterally are drained by the common iliac, the internal iliac, and external iliac lymph nodes.

## Innervation

The innervation of the ureters can also be divided into proximal, middle, and distal. The proximal nerve supply begins in the renal and aortic plexuses. The middle ureter is supplied by the superior hypogastric plexus, and the pelvic plexus provides innervation to the distal ureter. Visceral pain fibers are referred from the proximal ureter to L2 spinal nerve mostly, but they can also be carried to T11, T12, and L1 by the thoracic and lumbar splanchnic nerves that are part of the sympathetic nervous system. Stimulation of these sensory nerves (usually due to acute dilation of the ureter) results in referred pain to the dermatomes of T12–L2, namely the back and sides of the abdomen, the scrotum (males) or labia majora (females) and superior part of the anterior thigh. Peristaltic waves for ureteral contraction are controlled by pacemaking cells in the minor calyces and renal pelvis and are not dependent on autonomic stimuli [4]. Each minor calyx possesses these pacemaker cells, which can initiate a sustained contraction. These contractions are propagated away from the renal pyramid and toward the renal pelvis [12]. The duration of the contractile wave is dependent on the amount of urine being transported. With low urine flow rates the calyceal generated peristalsis may fail to precipitate generation of a pelviureteric peristalsis. With high urine flow rates, each contractile wave that reaches the pelviureteric junction is sustained and results in generation of a ureteral peristaltic wave and thus distal propulsion of urine toward the bladder. Specifically, the ureteric muscular coat is stimulated by the stretch of muscle fibers due to urine and thus peristalsis occurs [13]. The ureter makes an average three peristaltic contractions in a minute. There is debate on whether or not autonomic ganglia are present in the ureteric wall along its entire course as they have only have been identified in the very distal ureter [14, 15].

On a molecular level, activation of various S alpha-1-adrenoceptors 1A and 1D as well as muscarinic receptors have been found to cause ureteral contractions and have thus been the target of pharmaceutical manipulation [13, 16]. Efferent and afferent innervation from cholinergic, adrenergic, nonadrenergic, and noncholinergic receptors have also been identified, though the roles of the latter are not all completely understood [17]. Distribution of these different receptors is not evenly distributed throughout the course of the ureter, with the lower ureter being more densely populated than the upper ureter.

## Radiologic anatomy

Radiological imaging is important for planning endoscopic procedures as they provide a personalized anatomical guide that is specific to each individual patient. While excretory urography can provide a wealth of information about the ureter, new technological advances, namely computed tomography, have given our radiologic colleagues the ability to generate three-dimensional images of the urogenital system, which can provide opportunities for improved endourologic, laparoscopic, robotic, or open surgical planning.

The right kidney is situated 1–2 cm below the left kidney due to the liver. The renal pelvis and its relationship with the renal parenchyma can affect the configuration of the ureter at the UPJ. The renal pelvis, situated at the level of L2, can be intrarenal, extrarenal, or both. The ureter can exit the renal pelvis abruptly or with a gentle tapering where the beginning of the ureter and the end of the renal pelvis cannot be identified. The abdominal ureter descends from the renal pelvis vertically and begins to curve medially at the level of L5. Asymmetric medial deviation of the ureters at this level is considered a normal variant, and is often seen in young African American males [18]. However, deviation medial to the pedicles is considered abnormal. Likewise, lateral deviation of the ureters greater than 1.5 cm from the transverse processes is abnormal (Figures 38.3a,b).

From a lateral perspective, the ureters travel posterior to the anterior margin of the vertebral bodies. At the level of L4, they travel anteriorly past this margin, and at the level of L5, the ureters lie completely anterior to the vertebral bodies.

In addition to the normal anatomical narrowing of the ureters described earlier, there are several instances where narrowing can appear on excretory urography; thus it is important to distinguish imaging artifacts from true pathology. For example, normal peristaltic activity of the ureters can mimic a ureteral stricture. Comparing successive images temporally from the radiographic study usually results in normal visualization of the ureteral segment in question. At the levels of L3 and L5, an anterior oblique extrinsic narrowing is likely due to the gonadal vessels crossing the ureters. Similarly, narrowing of the ureteral lumen as it enters the pelvis is usually

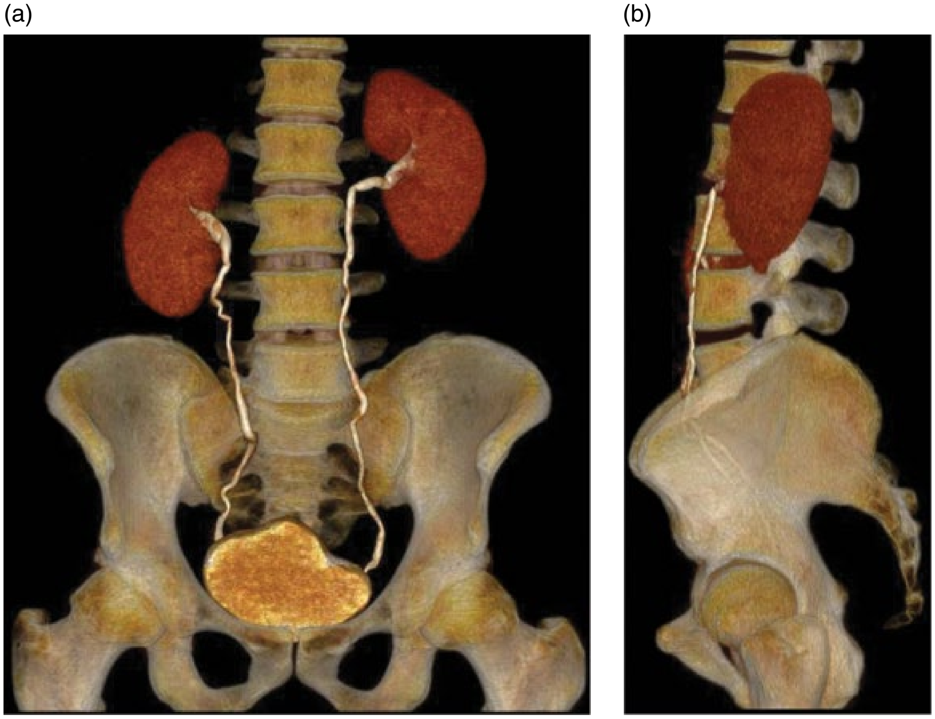

Figure 38.3 Three-dimensional imaging reconstruction of ureters using CT urography. (a) Anterior–posterior view, (b) lateral view.

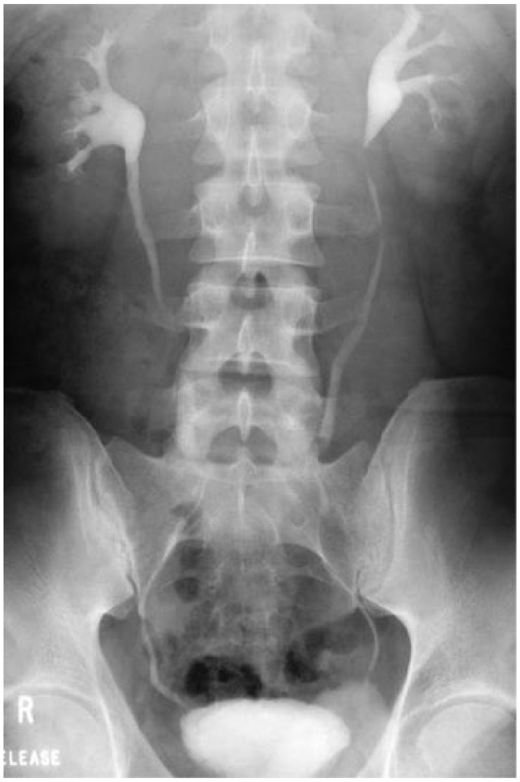

**Figure 38.4** Intravenous pyelogram of a patient with retroperitoneal fibrosis. Note the medial ureteral deviation typically seen at the L4–5 region.

secondary to extrinsic compression by the iliac vessels. Furthermore, kinks can appear in the abdominal ureters near the UPJ when inspirations cause kidney excursion, especially in patients with some redundancy of the ureter [19]. With bladder obstruction secondary to an enlarged prostate, ureters can truly be kinked at the distal end due to anterior displacement of the intramural ureter. This is identified as a "J hook" on urography [20].

Other pathologies can also be identified with urography. Asymmetric medial displacement of the intramural ureters can be caused by bladder diverticula, internal iliac aneurysms, and enlarged pelvic lymph nodes. Symmetric displacement of the intramural ureters medially (Figure 38.4) suggests retroperitoneal fibrosis [19]. An intraluminal mass can result in a filling defect known as the "goblet sign" and while most common with urothelial neoplasms, this proximal dilation can also be seen in benign processes such as ureteral fibroepithelial polyps.

## Endoscopic anatomy

When inspecting the bladder endoscopically the ureteral orifices at the UVJ are approximately 5 cm apart with the bladder full and about 2.5 cm in a decompressed bladder [6]. The ureteral orifices make up the lateral proximal border of the trigone and are located along the interureteric ridge (Mercier's bar), which is often more prominent in males than females. The superficial vessels coursing along the trigone point in the direction of the ureteral orifices and can assist the endoscopist in localizing and identifying the ureteral orifice.

The configuration of the ureteral orifice is classified into four structures based on visual appearance: grade 0 (volcano or cone shaped), grade 1 (stadium shaped), grade 2 (horse shoe shaped), and grade 3 (golf hole shaped) [21]. Grade 0 is most common and is considered normal while the other shapes are abnormal variations. The higher the grade of orifice configuration, the greater the likelihood to be displaced laterally and to be associated with vesicoureteral reflux (VUR) [22, 23].

The ureteral orifice normally effaces and compresses as the bladder fills, which is one of the mechanisms proposed in the prevention of reflux. Emptying the bladder in some instances can also assist in identifying the ureteral orifice and obviate the need for dilation prior to upper tract instrumentation.

Traumatic instrumentation or incision of the ureteral orifice can result in permanent reflux. Atraumatic dilation either with a catheter or balloon appears to not result in permanent reflux [24]. However, dilation of the ureteral orifices alone in some instances may be insufficient for passage of a ureteroscope to the upper tract due to an intrinsically narrow ureter. It is estimated that inability to pass the ureteroscope occurs in about 9% of cases [25]. There is ongoing controversy about the best method for access to the ureter and upper tract in this situation focusing on passive dilation with deployment of a ureteral stent and active dilation with use of a ureteric access sheath or balloon dilator [25–28]. Passive dilation with placement of a stent is arguably safer in terms of ureteral injury but requires a second attempt at ureteroscopy at a later time. Second attempts are mostly successful and seems to be based on the duration of stent [26]. Though active dilation with a balloon dilator or use of a ureteral access sheath can provide immediate access to the ureter, they are more traumatic to the ureteral walls, leading to local tissue ischemia and reperfusion injury that can result in scarring and strictures. The degree of ureteral wall injury when employing a ureteral access sheath for upper tract manipulation has been classified into five grades based on endoscopic findings: grade 0 (no lesion or mucosal petechiae), grade 1 (mucosal erosion without smooth muscle injury), grade 2 (injury to mucosa and smooth muscle with preservation of adventitium), grade 3 (injury to mucosa, smooth muscle, and perforation of adventitium), and grade 4 (total avulsion of ureter) [29]. High-grade injuries (grades 2, 3, and 4) were seven times more likely not to have had stenting prior to the use of the ureteral access sheath.

## Normal variations, congenital anomalies, and surgical alterations in ureteral anatomy

Congenital anomalies of the kidneys and ureters are relatively common and comprise about 20–30% of all congenital anomalies [30, 31].

### Deviation

Bilateral medial deviation of the pelvic ureters is considered a normal variant but can also result from retroperitoneal fibrosis, postsurgical changes, or pelvic lipomatosis. In retroperitoneal fibrosis, the upper collecting system is also dilated. When unilateral medial deviation of the ureter is present, it is more common on the right side and also more common in females due to uterine tilt to the left.

### Retrocaval ureter

In some circumstances, the right ureter can even deviate more medially and descend posterior to the inferior vena cava and then cross back the midline anteriorly to finish its course entering the pelvis over the iliac vessels. This variation is called retrocaval or circumcaval ureter.

### Ureteropelvic junction stenosis

UPJ stenosis is the abnormal narrowing at the site of the UPJ that potentially causes ipsilateral hydronephrosis and decreased renal function. The cause of the narrowing at the UPJ can be classified into intrinsic or extrinsic. Lack of adequate muscle fibers and increase in collagen fibers is one hypothesis of an intrinsic cause of UPJ stenosis. Failure of recanalization of the UPJ during development is another hypothesis [32]. Still yet another hypothesis focuses on extra tissue within the UPJ, causing a one-way valve picture resulting in difficulty draining urine. Other possible etiologies of UPJ stenosis may be persistence of valves during elongation of the ureter during fetal development. Extrinsic causes of UPJ stenosis or obstruction include crossing vessels, bands, kinks, high insertion of the ureter, or acute angulation.

### Agenesis

Renal agenesis occurs if the metanephric diverticulum fails to penetrate the metanephrogenic blastema. The result is that the collecting system does not induce the formation of nephrons.

### Duplicated systems

Normally, the ureters develop embryologically from a single ureteric bud. If there are two ureteric buds on one side during development, it is possible for any part of the collecting system to be duplicated. The collecting system can be duplicated both partially and completely. Partial or complete duplication is the most common ureteral anomaly with an overall incidence of 0.6–0.8% [31, 33, 34]. The Weigert–Meyer rule states that in a completely duplicated system, the ureteral orifice of the upper pole moiety empties into the bladder in a position that is medial and inferior to the ureteral orifice of the lower pole moiety (Figure 38.5).

Bifid ureters result from incomplete division of the metanephric diverticulum and ureteric bud during development, resulting in a bifid kidney. Complete division of the metanephric diverticulum results in a supernumerary kidney. The ureters draining the orthotopic kidney and the supernumerary kidney can be completely separate or be partially duplicated as a bifid ureter.

### Ectopic ureters and ureteral orifices

During fetal development, the ureteric bud is derived from the wolffian duct and normally separates from each other. The ureteric bud migrates cephalad while the wolffian duct migrates caudally. If the ureteric bud does not separate from the wolffian duct, then it can be pulled to migrate caudally as well. This is the reason that ectopic

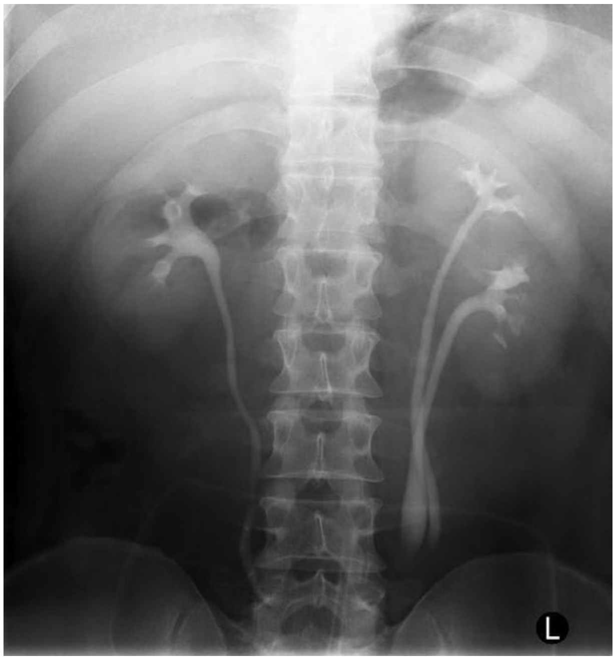

**Figure 38.5** Intravenous pyelogram demonstrating left duplicated collecting system and ureters.

ureters are more commonly caudally ectopic. These ectopic ureters can empty into the lower bladder, urethra, vestibule, or vagina in females and posterior urethra, seminal vesicle, vas deferens, or ejaculatory duct in males.

### Ureterocele

A ureterocele is an abnormal sacculation of the intramural ureter that is often caused by a congenital stenotic ureteral orifice, producing upstream dilatation [22]. Access to a ureter with a ureterocele may require dilation of the orifice. Ureteroceles are associated with duplicated systems and typically are associated with the ureter of the upper pole moiety [35]. Since complete duplication is seen more commonly in females, ureteroceles are concomitantly more common in females compared to males. It is not uncommon for patients to develop a urinary stone in a ureterocele, which may require an incision for removal (Figure 38.6a,b).

### Ureters of neobladders and conduits

As there are no anatomical landmarks in neobladders or urinary conduits, identifying the ureteral orifices of these ureters can be a challenge. Use of flexible ureteroscope for retrograde ureteroscopy is both easier and safer given unclear anatomy and potential to injure structures [36]. If possible, placement of antegrade guidewires percutaneously can address these issues.

### Reimplanted and reconstructed ureters

Reimplantation of a ureter is most often performed in children for VUR. There are various techniques for reimplantation with some reimplanting the ureter in its orthotopic position while others not (Figure 38.7).

### Ureters of malpositioned or fused kidneys

In normal development, the kidneys migrate cephalad from the pelvis into their retroperitoneum positions. They begin with the pelvis anteriorly and calyces posteriorly; as the kidneys ascend, they rotate 30° so that the pelvis faces medially. If kidneys fail to ascend, they remain in the pelvis and are often malrotated. Their ureters exit more laterally and are highly inserted; they can also be tortuous.

Fused kidneys may be located anywhere along the path of normal ascent of the kidney. The most common renal fusion anomaly is a horseshoe kidney. A horseshoe kidney has abnormal fusion of the lower poles of the two renal units resulting in an isthmus of functioning or nonfunctional renal parenchyma. This renal isthmus limits the kidney's fetal ascent of the horseshoe kidney at the level of the inferior mesenteric artery. In addition to abnormal ascent, the fusion prohibits the proper rotation of the kidneys, typically resulting in a high and lateral insertion of the ureter at the level of the UPJ.

Fused kidneys occur due to abnormal fusion of the metanephric blastema during embryogenesis and can also result in abnormal ascent of the kidneys. Crossed fused renal ectopia refers to an anomaly where the kidneys are fused and located on the same side of the midline. The estimated incidence is around 1 out of 1000 births [37]. There is a recognized male predilection with a 2:1 male to female ratio. More than 90% of crossed renal ectopia results in fusion and failure of the kidneys to reach their appropriate positions at the level of L2 in the eighth week of fetal life.

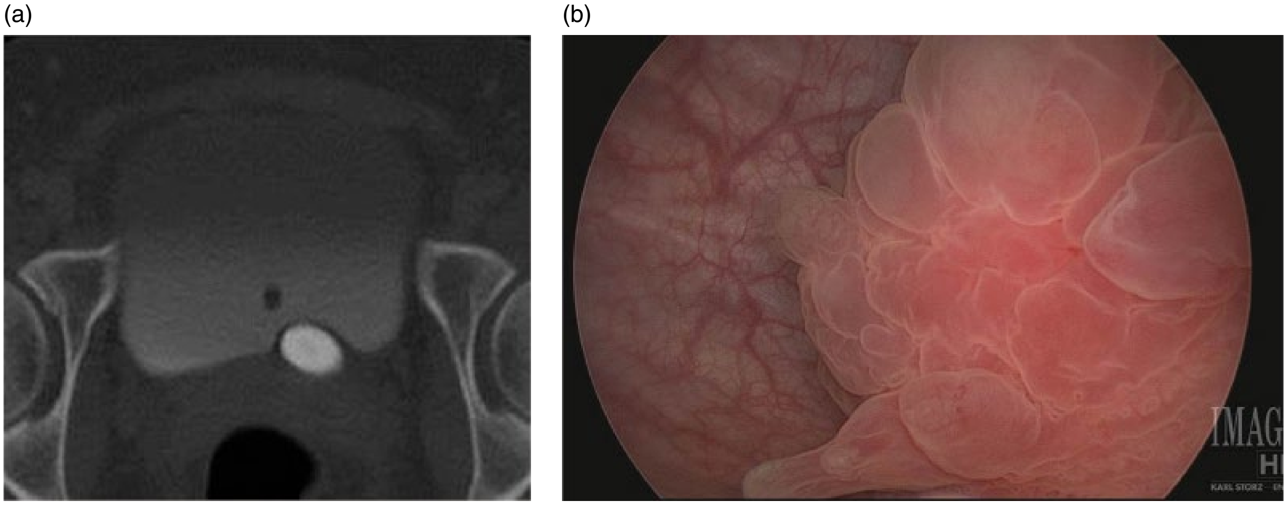

**Figure 38.6** (a) CT image of left ureteral stone in a simple ureterocele. (b) Endoscopic view of an inflamed left ureterocele. The ureteral orifice was identified and required an incision to remove the stone.

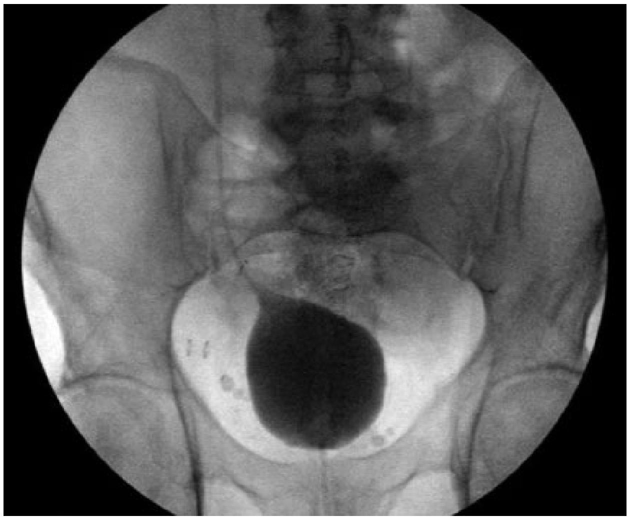

**Figure 38.7** Ureteral reimplant to the bladder dome.

Some evidence supports that an abnormally situated umbilical artery prevents normal cephalad migration. Another theory is that the ureteric bud crosses to the opposite side and induces nephron formation in the contralateral metanephric blastema. The result is a single renal mass with two collecting systems being located on one side of the abdomen. There are several subtypes of crossed renal ectopia based on the appearance of the fusion abnormality: inferior crossed fusion, sigmoid kidney, lump kidney, disc kidney, L-shaped kidney, and the superiorly crossed fused (Figure 38.8) [37]. Left-to-right ectopy is thought to be three times more common. Of note, the trigone retains its anatomic integrity with the involved ureter draining the ectopic renal unit into the correct corresponding contralateral ureteral orifice.

## Key points and conclusions

Intimate knowledge of the ureter and its associated structures remains critical in endourology. Advancements in endoscopy and imaging have facilitated numerous procedures for urologists. Three-dimensional reconstitutions in particular can help map urogenital systems that have undergone complex reconstruction. However, even without these adjuncts, understanding of the normal ureteral course can help make endoscopic procedures proceed without complications and help identify true abnormalities versus normal variants.

## Introduction

The natural progression from open surgery to minimally invasive procedures is a testament to the technological evolution that has brought about the modern day ureteroscope. Young performed the first recorded ureteroscopy in 1912 using a 9.5 Fr pediatric cystoscope [1]. Since then, advancements in endoscopic design and the use of fiber-optic technology has led to smaller scopes with improved maneuverability, allowing for not only rigid and semirigid ureteroscopes, but also flexible ureteroscopes. The latest generation of ureteroscopes now provides high-definition digital images of the ureter and intrarenal collecting system, allowing procedures to be carried out safely, with high success rates and minimal morbidity in adults and children.

To appreciate how rigid and semirigid ureteroscopes have evolved through time, this chapter will portray a summary of key technical developments, starting with the first endoscope, the effect of changes in instrumentation, and progressing through to the latest digital technology. A description of key features of ureteroscopes is then given, discussing their similarities and differences and potential future trends for their further development.

## Rigid and semirigid ureteroscopes

### Rigid ureteroscopes

**Historical perspective**

The history of the endoscope dates back to 1853 [2–4] and has developed considerably to the present day ureteroscopes (Table 39.1). The traditional components required to carry out a rigid endoscopic procedure are the telescope with working channels for irrigation and instrumentation, a light source, optics to convey the image, and a camera system to capture the image. This has been revolutionized by the use of fibroptic technology; however, with the increasing speed of technological evolution, fiber-optics will one day make way for the digital era.

The forerunner of the endoscope can be traced back to 1806 with the construction of the light-guiding instrument or “Lichtleiter” by Phillip Bozzini for direct inspection of internal organs [5]. This scope was basic in design, consisting of a direct vision hollow tube through which candlelight was transmitted by a mirror. The French surgeon Antoine Jean Desormeaux further developed the Lichtleiter, producing the “endoscope” in 1853 using a system of mirrors and lens, and a kerosene flame to provide light to examine the urethra and bladder (Figure 39.1). Gustave Trouvé further upgraded indirect illumination by candlelight to electrical illumination using glowing heated platinum wires at the tip of the instrument in 1873 [5]. The filaments were later replaced by Edison’s incandescent lightbulb. The Nitze-Leiter cystoscope, a rudimentary version of the modern cystoscope, was constructed in 1879 and incorporated a simple lens system into the viewing tube [5].

Fiber-optic lighting technology was introduced in the 1960s, replacing the incandescent bulb and revolutionizing the manufacture of rigid endoscopes. The design was based on the principle of total internal reflection: when light travels in a transparent medium such as glass, internal reflection of the light occurs at the interface between the medium and its surroundings, as demonstrated by John Tyndall in 1854 [6]. This physical property of internal reflection allows the “bending” of

light within flexible glass. Thus, light travelling inside a small-diameter flexible glass fiber surrounded by cladding of lower refractory index can be transmitted over a long distance with minimal degradation. The benefit of modern fiber-optic lighting is greater illumination by cooler light, ultimately making it safer. An additional benefit is that the scopes can be made with a smaller profile shaft, allowing more room within the shaft for the addition of an irrigation and instrument channel. The fiber-optic cable is often attached via a light post to the endoscope, but may alternatively be built into the design of the scope.

The innovative work of the British physicist Harold Hopkins led to the next major breakthrough in rigid endoscopic design with the introduction of the rod–lens system in the 1960s [7]. Until then, the shaft of the scope consisted of a hollow tube with a series of thin relay lenses separated by long air spaces. The relay lenses had to remain in precise alignment and any displacement of the lens resulted in a significant loss of image transmission. There was also a significant loss of light transmission with this system. Hopkins replaced the thin relay lenses within the shaft of the endoscope with long, contoured glass rods acting as the transmission medium, while the thin pockets interspersed between the glass rods acted as lenses. With the telescope primarily being made of glass, which has a higher refractive index than air, light transmission could be increased ninefold over previous lens systems, with the additional benefit of reduced image distortion and a wider viewing angle. The outer diameter of the endoscope shaft could also be reduced, paving the way for the development of the rigid ureteroscope and the introduction of working channels. The old lens system was notorious for its lack of durability and the Hopkins rod–lens system produced a significant improvement in this area. There were a few apparent weaknesses in the rod–lens design: any deviation in the use of the cystoscope from being used in straight lines, as can occur with the application of torque to the shaft, could lead to misalignment of the rod–lens setup and the permanent disappearance of up to half the image. The problem manifests itself as a half-moon or crescent-shaped defect when viewing through the scope eyepiece. This design flaw would be seen to be disadvantageous in the passage of the endoscope through the natural undulations of the ureter. A further consideration for ureteroscopic design centers on the diameter of the lens that dictates the size, or degree of magnification, of the image; the reduced diameter of the ureteroscope would inadvertently have a smaller image than the larger cystoscope.

## Endoscopic evolution

Young undertook the first recorded ureteroscopy in 1912, and it took another 65 years before Goodman [8] and Lyon et al. [9] ventured into the ureter, performing distal ureteroscopy in both male and female patients (Table 39.2). Goodman reported using an 11 Fr pediatric rod–lens cystoscope to inspect the distal ureter in three adults [8]. In one of these patients, a distal ureteral tumor was fulgurated, marking the first ureteroscopically treated tumor. Lyon et al. reported ureteroscopy in five adults using sound dilators for ureteral dilation before passing an 11 Fr pediatric cystoscope [9]. However, most of these early ureteroscopy patients were women. Lyon et al. reported in 1979 the use of specially designed ureteral dilators attached to the tip of a flexible probe. They were able to dilate the orifice to 16 Fr, permitting insertion of a standard-length 13 Fr cystoscope for distal ureteroscopy in men. These early investigators demonstrated the ease and safety of rigid ureteroscopy for the distal ureter in both sexes.

The first rigid ureteroscope specifically designed for ureteric use was produced in 1979 by Richard Wolf Medical Instruments and was used by Lyon et al. [10]. Modeled on a pediatric cystoscope, this 13 Fr instrument had a working length of 23 cm and sheath sizes of 14.5 and 16 Fr; a 16 Fr resectoscope sheath was also available. The 13 Fr sheath was used only for inspection, but the larger sheaths allowed simultaneous passage of a ureteral catheter or basket for stone manipulation and removal. For the first time, ureteral calculi were visualized, engaged in a basket, and removed [10, 11]. A longer ureteroscope that could reach the renal pelvis was developed by Enriqué Pérez-Castro in collaboration with Karl Storz Endoscopy in 1980 [12]. Its 39 cm length allowed inspection of the renal pelvis for the first time.

Further ureteroscopic modification was not due to advances in scope technology, rather the introduction of and progression in instrumentation. The launch of ureteroscopic ultrasonic lithotripsy for the treatment of urolithiasis led to modifications in ureteroscopic configuration. Initially, the probes were hollow and 8 Fr in diameter, requiring removal of the telescope and blind stone lithotripsy. These were replaced by smaller solid probes (1.5–2.0 mm) that could pass through the working channels but that were too rigid to negotiate the angles of the instrument working ports. This led to the development of the offset eyepiece which allowed the direct passage of the probe through a straight working channel under direct vision. Rigid ureteroscopes were later designed with an interchangeable offset eyepiece and standard telescope, allowing easier passage of the scope. Due to difficulties and complications from inserting rigid rod–lens type ureteroscopes with diameters approaching 14.5–15 Fr, it became apparent that smaller ureteroscopes were needed. With the availability of smaller working instruments, Huffman described a compact ureteroscope that was 8.5 Fr in diameter and had a working channel of 3.5 Fr [13]. The rod–lens telescope was integrated into the ureteroscope, which helped decrease the outer diameter while maintaining a good-sized working channel.

## General properties

The rigid ureteroscope has not deviated significantly from the original pediatric cystoscope used to inspect the ureter. Any development has centered on the

**Table 39.2** Landmark evolutionary steps in the development of the rigid ureteroscope.

| Year | Pioneer | Rigid ureteroscope technological advances |
|---|---|---|
| 1977 | TM Goodman and Edward Lyon | Provided the first reported series of distal ureteroscopically performed cases |
| 1979 | Richard Wolf | Credited with the design and construction of the first rigid ureteroscope |
| 1980 | Enriqué Pérez-Castro | Developed the “long” ureteroscope in collaboration with Karl Storz Endoscopy |
| 1980 | ACMI | The Rigiflex was the first ureteroscope to adopt the use of fiber-optics to allow the “gooseneck” eyepiece |
| 1989 | Huffman | Produced the 8.5 Fr “compact ureteroscope” with a 3.5 Fr working channel. The rod–lens was integrated into the ureteroscope |

improvement in the light source, the introduction of the rod–lens optics system, the launch of a single working channel, and changes in the overall ureteroscope dimensions. That said, over the years the ureteroscope has become narrow enough to ensure easier ureteric access and long enough to venture into the renal pelvis, and has a working channel to allow instrumentation for intervention and diagnostic purposes.

#### Optics, angle, field of view, and eyepiece

The rod–lens systems has provided excellent optical quality over the years, but scopes incorporating this design tend to have larger diameters and are prone to damage following angulation of the ureteroscope. The “angle of view” in an endoscope can vary from 0°, providing a straight view of the structure in question, to 70°, which allows inspection of tissues at an oblique angle from the straight axis. These rod–lens ureteroscopes were either interchangeable (from 0 to 70° angle of view) or integrated within the ureteroscope itself. The 70° lens was primarily used to inspect the renal pelvis and calyces, although these lenses are now virtually obsolete with the development of flexible ureterorenoscopes. The few current rod–lens ureteroscopes have integrated telescopes because of their smaller size advantage, and the angle of view through the objective lens is fixed at 0–5°. The advantage of a slight angulation on the direct vision lens is easier and quicker visualization of working instruments being passed out of the tip, reducing the potential for inadvertent iatrogenic injury to normal urothelium. The “field of view” is often quoted for ureteroscopes and is the entire view seen by the eye when it is trained in any particular direction. For endoscopes, this can vary from 60° to 90°, depending on the type of instrument.

Ureteroscopes had a standard eyepiece design, which sees the ocular lens drawn in a straight line through the shaft of the scope (Figure 39.2). When rigid ultrasound probes were first introduced for ureteroscopic lithotripsy, an offset ocular configuration was trialed that allowed for direct access to the instrumentation port, allowing easy entry and removal of rigid accessories without impairing the view of the scope.

#### Dimensions and sheath tip

From the earliest days of ureteroscopic evolution, the diameter of the rigid scope has come down from 16 Fr to 8.5 Fr, while the length of the scope ranges from 25 to 54 cm, allowing the ureter and renal pelvis to be accessed. Early ureteroscopes had beaked tips emulating early cystoscopes, which could result in ploughing of the ureteral epithelium. This was replaced with the current beveled tip designs to provide safer and easier advancement into the ureter (Figure 39.3).

#### Working channel

The single channel in most rigid ureteroscopes varied in size from 3.5 to 5 Fr, a range dictated by the size of the largest of instruments available at the time. The working channel was triangular in cross-section and allowed irrigation to continue around the sides of any deployed instrument within. Ureteroresectoscopes incorporated manually working elements much like standard transurethral resectoscopes. Working elements included resecting loops, cold and hot knife blades, and fulguration electrodes.

## Semirigid ureteroscopes

#### Endoscopic evolution

Developed in the early 1980s, the Rigiflex ureteroscope by ACMI had a straightened eyepiece for introducing the scope into the ureter and later offset to admit the ultrasonic lithotripter. The ACMI HTO-5 was unique in being the first ureteroscope to incorporate fiber-optic imaging technology to produce the flexible “gooseneck” eyepiece. Although the scope had a 12.7 Fr diameter shaft and a 5 Fr single working channel, comparable rod–lens ureteroscopes of the time with a 5 Fr channel were 14.5–15 Fr in size.

Ureterorenoscopy with a rigid scope still had inherent problems with the rod–lens optics due to the tortuous nature of the ureter and the caliber and working length of the instrument, which gave impaired vision. With the growing demand for rigid ureteroscopes in the 1980s, the further use of fiber-optic technology enabled further miniaturization of the shaft diameter along with reduction in size of the working channels. The “miniscope” or semirigid ureteroscope combined smaller working channels and fiber-optics, allowing both illumination and image incorporated into a metal sheath. The optical system was reduced in size compared with the rod–lens design, leading to its primary advantage, an overall reduction in the outside diameter of the scope, but not at the expense of reducing the size of the working channels.

Although the rigid rod–lens system provided excellent optical quality, an additional advantage of the miniscope was that the fiber-optic bundles within the metal shaft could be flexed significantly without distortion of the image and the appearance of a dark crescent-shaped area that can occur with excessive torque applied to the rod–lens telescope. Such flexibility allows easier passage of the scope through the intramural ureter and then anteriorly over the iliac vessels with great maneuverability to negotiate narrowed or strictured ureters. Other advantages of the miniscope included easier access, reduced requirement for ureteric dilation, and decreased ureteric injury.

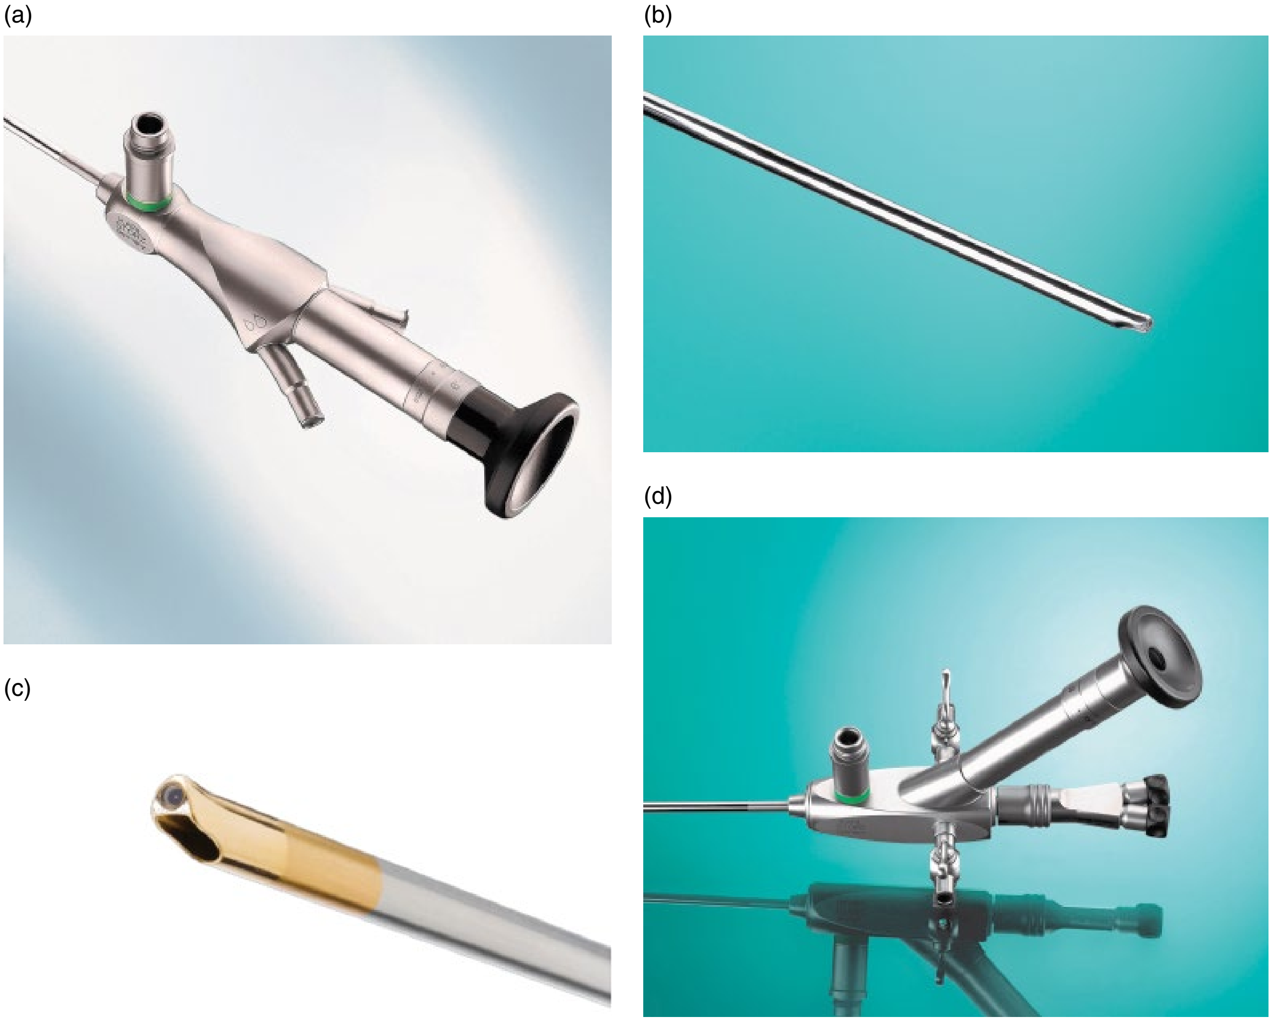

**Figure 39.2** The Storz (a, b) and Olympus (c, d) series demonstrates the available eyepiece designs. These facilitate both easy insertion under direct vision with the (a,c) standard design, as well as the ability to use the straight rigid accessories in comfort with the (b, d) oblique offset designs. *Source:* (a, b) Karl Storz GmbH & Co. KG, Germany. (c, d) Olympus Medical, UK. Reproduced with permission of Karl Storz GmbH (a, b) and Olympus UK (c, d).

The first available "miniscope" was Candela Laser Corporation's semirigid ureteroscope, as described by Dretler and Cho in 1989 [14]. It was the first to incorporate two independent working channels, one for an accessory and one for flow, each of 2.1 Fr size. It was the success of this 41 cm instrument with a 7.2 Fr distal section that established it as the benchmark instrument of its time and prompted other US manufacturers to develop competitive instruments of similar design, such as the MR-6 ureteroscope from ACMI. The MR-6 proved to be much more durable than the Candela scope and quickly gained supremacy [15]. It had a sub-7 Fr distal section with larger throughput capacity of one 2.3 Fr and one 3.4 Fr device in separate channels. The final distal shape was determined by enclosing the smallest size optical system the engineers could conceive at the time, along with the two separate throughput channels in a triangular-shaped outer tube, giving a 6.9 Fr distal section. For the image system, by designing a conventional glass objective coupled to a 0.5 mm diameter fused quartz fiber bundle, more individual pixels of optical information were provided than the etched glass fiber bundle in either the Candela or the HTO-5 scopes. It came in a short 33 cm length version to allow access to the distal ureter and up to the ureteropelvic junction (UPJ) of females. The MR-6L was 41 cm long and was intended for use primarily in males and obese patients. Over the past decade, mini-ureterosopes or semirigid ureteroscopes have been refined in terms of materials, ergonomic layout, fiber-optics, and camera systems,

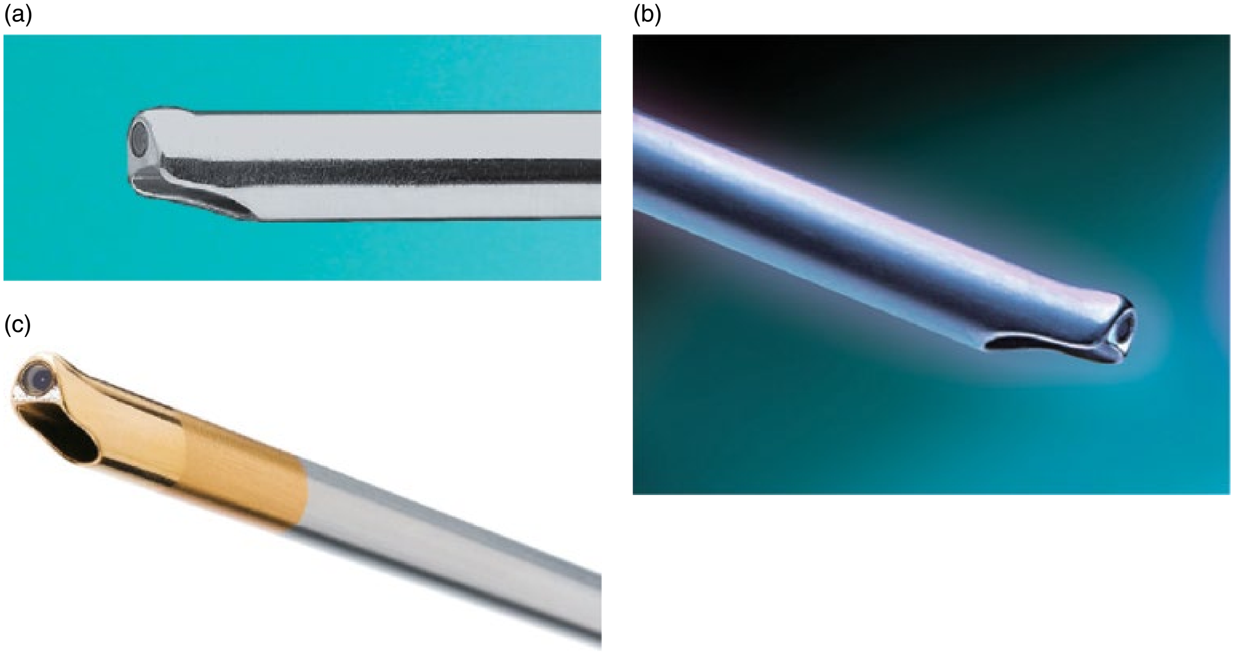

**Figure 39.3** Ureteroscope atraumatic distal tip. The tips generally come beaked, beveled, or flat, as each manufacturer argues a case for easier atraumatic negotiation of the ureteric orifice. *Source:* Karl Storz GmbH & Co. KG, Germany and Olympus Medical, UK. Reproduced with permission of Karl Storz GmbH and Olympus, UK.

though there have been no significant steps forward in scope evolution. They remain the most commonly used type of ureteroscope [16].

### Optics and eyepiece

In practice, the rod–lens ureteroscope offers quality images, but allows only limited vertical deviation on advancement and is suited in ureters that require only minimal change in direction. The introduction of fiber-optic bundles within a rigid shaft has enabled navigation through the more challenging tortuous ureter without leading to optical malfunction. Although earlier fiber-optic image bundles were disadvantaged by a characteristic graining effect, the pixel density in most current semirigid ureteroscopes has now increased beyond 30 000, such that the images are large and bright and are much closer in quality and size to those of the traditional rod–lens system. Newer fiber-packing techniques and advanced camera systems have led to further improvement. Fiber-optic systems now provide light and image transmission through most current semirigid ureteroscopes.

As discussed earlier, offset eyepieces became necessary when rigid ultrasound probes were developed for ureteroscopic lithotripsy. These probes, as well as larger, more rigid working instruments, required a straight working channel for passage through the scope. Offset eyepieces can either be fixed or moveable and can be either angled or offset, although always straight and parallel to the ureteroscope shaft. The angle of view is usually 0–5°.

### Dimensions and sheath tip

It is important for ureteroscopic design and procedural success that the scope is narrow and flexible enough to deal with the changing caliber of the ureter, with areas of natural lumen reduction at the UPJ, iliac vessels (12 Fr), and vesicoureteric junction (3–10 Fr), along with potential pathologic narrowing. Instrument manufacturers have made attempts to reduce the trauma of insertion by modifying shaft design. The mini-ureteroscope shaft has a graduated stepped design, starting with a distal tip diameter as small as 6.9 Fr [15], rising up to 13 Fr in the larger scopes. This ensures maximal proximal strength of the scope while providing a gradual dilation of the ureter as the scope is advanced. The continued reduction in ureteroscope diameter has led to a reduction in the number of ureteral strictures seen and an increased success rate for the procedure [17]. Furthermore, the profile of the semirigid ureteroscope beveled tip is designed to ensure minimal iatrogenic damage to the ureteric orifice and urothelium while maximizing the successful passage of the ureteroscope into the ureter (see Figure 39.3). The semirigid ureteroscope is generally manufactured in two lengths. A “short” ureteroscope of just over 30 cm can be used to access up to the level of the mid ureter in males and renal pelvis in females. To reach the renal pelvis in a male requires a “long” ureteroscope of 40 cm or more.

#### Working channel

Advances in construction of the miniscope led to the option of either a larger diameter single working channel with one large space for both irrigation and instrumentation to run through, or two separate working channels allowing separate instrumentation and irrigation. A larger single channel permits the use of larger instruments and possible removal of small stone fragments or biopsy specimens through the sheath, and dual instrumentation depending on the limits of each channel port. Two separate channels allow the operator to work through one channel without impeding irrigation flow through the other. The diameters of the two separate working channels range from 2.1 to 5.4 Fr, but are usually 3.4 Fr, allowing the introduction of a more rigid 3 Fr instrument and 2.4 Fr for irrigation or a second accessory. The channels are either triangular or oval in cross-section, which allows irrigation to continue around the sides despite the placement of an accessory instrument.

The introduction of holmium laser lithotripsy for the treatment of upper urinary tract stone disease in 1996 [18] was a revolutionary leap forward in endoscopic stone treatment, and is now the bedrock of contact lithotripsy in most departments. With fiber diameter measuring only 200 and 365 μm, this has virtually abolished the requirement for anything larger than a 3.4 Fr channel, allowing smaller outer diameter ureteroscopes to be used with better flow and therefore better vision. The narrow lasers also allow them to be used simultaneously with another accessory down a working channel, while still maintaining some flow.

#### Camera and video systems

Image transmission has evolved in line with changes seen with the semirigid ureteroscopes. Although images are occasionally viewed directly from the eyepiece due to technical problems or, rarely, the surgeon's preference, it has been conventional for some years to use indirect imaging on a television monitor using a video system. The video camera and monitor-based endoscopes allows binocular vision that is projected onto a large television monitor; this is ergonomically easier for the urologist and also can be enjoyed by the theater team. The high-resolution image output has also reduced the discrepancy between the better images obtained with the larger endoscopes compared with those previously seen with the ureteroscope.

Analog images produced by transmission down fiberoptic bundles continue to be the main pathway to deliver views of the subject matter to the camera in the majority of semirigid ureteroscopes. The drive to engineer semirigid ureteroscopes with digital distal sensor chip technology to produce high-quality digital images has not yet taken off to the same degree as seen with the flexible scopes. This is partly due to the high density of fiber-optic bundles that can be incorporated into the semirigid ureteroscope, which are more resistant to image degradation when compared to those found in the flexible ureterorenoscope. Olympus produce the only digital semirigid ureteroscope, called the EndoEye video ureteroscope (also known as the Oes Pro Video), which has a distal charge-coupled device (CCD) video chip (see Table 39.3).

#### Irrigation

An effective irrigation system is important to optimize the chance of access into the ureteric orifice and provide good visibility during either rigid or flexible ureteroscopy. The simplest arrangement involves gravity irrigation, which has to contend with the small diameter and long length of the ureteroscope, causing a reduction in flow. Other configurations are available that generate a greater pressure and therefore flow, with the pneumatic sleeve applied around the bag of fluid being the most common semi-automated setup. Devices requiring operator/assistant input to supply increased flow on demand include attaching two 60 ml syringes via a Y-connector to inject irrigation as needed, and the Peditrol irrigation device that delivers a bolus via a foot pedal [19]. Automated infusion systems offering continuous saline irrigation, such as the Ureteromat, also exist which require no input from the endoscopist. The more recent continuous-flow ureterorenoscope (10.5 Fr) promises to provide a 100 times higher flow capacity while preserving the intrarenal pressure compared with conventional ureteroscopy *ex vivo* [20].

## Current ureteroscopes

Rigid ureteroscopes are available in many of the designs previously described. The characteristics of the latest designs of currently available semirigid ureteroscopes are given in Table 39.3.

### Care, maintenance, and technical failure

An important consideration when weighing up the purchase of a new ureteroscope is its longevity, and there is often a balance to be sought between optimal duration of scope life and its efficacy. Although less of a problem with the semirigid ureteroscope in comparison with its flexible counterpart, applying excessive torque causing deflections over 5 cm can lead to significant image distortion and scope failure. The majority of ureteroscopic failures are attributed to iatrogenic causes, including improper handling at the time of instrumentation and problems during the sterilizing process [21]. Regardless of the type and make of ureteroscope, the frequency of

**Table 39.3** Specifications of currently available semirigid ureteroscopes.

repair increases with decreasing ureteroscope diameter and increasing length of instrument [22]. Previously, with stepped shaft design of the rigid ureteroscope, bend stress was concentrated at solder points. Newer tapered shafts were produced to reduce this problem, making them more durable and less traumatic. Other notable risk factors for predicting the number of uses expected from a ureteroscope are its age and whether the ureteroscope has undergone comprehensive repair as a result of prior damage [21]. For optimal scope life, it is important that optimal care is taken in looking after the instrument and cleaning procedures are carried out with strict adherence to company instructions.

## Future trends

The digital video endoscope is now here to stay and the endless possibilities using this technology are just starting to be realized. With further improvements in materials and endoscope design, the ability of the endourologist of tomorrow to diagnose and treat pathologic conditions affecting the urinary tract will continue to improve. It will not be long before all major endoscope manufacturers produce a distal sensor ureteroscope, and the endoscope of the future, whether rigid or flexible, will contain no viewing lens component. Further progress in digital technology will ensure further reductions in shaft diameter and the addition of increased functions, including wireless transmission of images to high-definition PC monitors, and potentially portable ureterorenoscopes. It remains to be seen whether these changes will result in improved durability.

### Three-dimensional ureteroscopy

Current endoscopic systems provide an image output in two dimensions with stereoscopic or three-dimensional (3D) imaging existing only in the domain of robotic and, rarely, laparoscopic surgery. With miniaturization of the CCD chips and future reduction in the cost of this technology, positioning two of them in the distal tip of the scope would enable stereoscopic images to be created with true depth perception. The advantages of 3D imaging during ureteroscopic procedures however, have not been confirmed and the additional costs may not be offset if the benefits prove to be small.

### Virtual ureteroscopy

The use of virtual endoscopy for computer-driven reconstruction has been applied to multiple sites in the human body where there is a hollow viscus, including the renal collecting system and ureter [23, 24]. Although it is early days for this technology, this technique may prove to be useful as a noninvasive way of surveilling the urinary tract.

# Flexible Ureteroscopes

*Vincent G. Bird & John M. Shields*

*Department of Urology, University of Florida, Gainesville, FL, USA*

## History and evolution

The flexible ureteroscope is a versatile and ever-improving instrument utilized by many urologists. As the technology of flexible ureteroscopes improves, the indications for which it is used increase, pushing the boundaries of its capabilities and paving the way for further innovation. Due to cost concerns relating to the fragility of these endoscopes, manufacturers have recently endeavored to produce less expensive, disposable versions of these highly technologically advanced instruments [1–4]. In response to ergonomics and operator use concerns, manufacturers have also developed remote operator/robotic platforms for use with flexible ureteroscopes [5–7]. These latter ideas are now being clinically tested for feasibility and practicality.

The history of the evolution of flexible ureteroscopes involves many aspects of engineering, evolving technologies, and issues that relate to their practical clinical use. Although many of the technologies and earlier models of flexible ureteroscopes discussed herein are no longer in regular use in many parts of the world, an understanding of their working paradigms is critical to understanding proper and most effective use, possibilities and limitations, and risk for damage that can occur.

## Components

All flexible ureteroscopes require a number of key components. Similar to all rigid ureteroscopes, flexible ureteroscopes require a mechanism for optics, lighting, irrigation, and channels for passage of instruments, all of which need to be configured within a small-diameter shaft in order to traverse the narrow ureter. Flexible ureteroscopes also require an ability to manipulate the direction of the distal tip in order to negotiate the course of the ureter, renal pelvis, and calyces. Another requirement for these fragile instruments was demonstration of durability, including the ability to withstand repetitive extensive torqueing as well as sterilization and processing. As outlined in the ensuing discussion, it will become evident as to how modern flexible ureteroscopes have evolved, and continue to evolve, through sequential generations of design and function to optimize their function, control, and ability within the smallest diameter shaft allowable.

## Optics and illumination

To design a flexible ureteroscope that can fully navigate the ureter and its nonlinear and often tortuous anatomy, as well as the renal pelvis and its calyces, the ureteroscope must be flexible with an ability to bend extensively without significant compromise in function, have the ability to manipulate the direction of its distal tip by the operator, transmit sufficient light to the operative site, and transmit the image of the operative site to the operator in a highly reliable manner. The application of fiber-optics was critical to the development of a flexible ureteroscope, as fiber-optics enabled the transmission of imaging as well as the transmission of light across a medium that could bend, twist, and turn. Although current production of flexible ureteroscopes is focused on digital technology, fiber-optic ureteroscopes are still in use today and are an integral part of the history and understanding of their evolution.

Fiber-optic flexible ureteroscopes are made up of bundles of individual fibers in parallel sequence. The image

Companion website: www.wiley.com/go/smith/textbookofendourology

at the distal end of the fiber-optic is transmitted via the fiber to the proximal end with identical perception and orientation. The fibers make up a composite of the image on a whole and thus give a honeycomb appearance to the final image, also known as the Moiré effect, due to the arrangement of the bundle of fiber-optics (Figure 40.1). This final image is seen through an eyepiece and can be observed with the naked eye through a lens or transmitted to a television or computer screen via a camera. Fiber-optics are also used to transmit light from the proximal end of the scope to the distal end in a similar fashion, thus illuminating the working field. Due to the flexible nature of these bundles of fibers, the ureteroscope is able to bend and turn without altering the image or lighting quality. Nonetheless, the image quality of even the most modern fiber-optic ureteroscopes remains inferior when compared to the rod–lens system of rigid ureteroscopes [8]. To improve the quality of the image with a flexible ureteroscope, the number and diameter of the fiber-optics must be increased. However, this leads to an increase in diameter of the shaft of the ureteroscope, limiting its ability to access the upper urinary tract, its flexibility, and size of irrigation and working channels [9, 10].

The fiber-optics within ureteroscopes produce an image that is “grainy” with regard to clarity because of the Moiré effect. These fibers are also disposed to fracturing with wear and tear, and water can leak into the lens, compromising image quality (Figure 40.1) [11]. Thus, even though the inclusion of fiber-optics was critical in the development of flexible ureteroscopes, it also contained inherent engineering limitations.

## Digital flexible ureteroscopes

More recently, digital imaging systems have been introduced into the design of flexible ureteroscopes. Charge-coupled devices (CCD) and complementary metal-oxide semiconductor (CMOS) sensors were first used on the cameras mounted to the lenses of fiber-optic flexible ureteroscopes, aptly referred to as “chip-on-the-tip” technology, allowing transmission of images in digital format, leading to a crisper and cleaner image compared to analog video. Within the last few years, however, there has been significant miniaturization of this technology. Now the CCD and CMOS sensors are small and powerful enough to be placed at the distal tip of the flexible ureteroscope, obviating the need for any fiber-optics. Rather than using an external light source which is transmitted via fiber-optics, these ureteroscopes use light-emitting diodes present at the tip to provide a light source. The image transmitted through the distal lens is then processed either at the tip of the ureteroscope or within a remote device prior to being transmitted and projected on a monitor. With the removal of the fiber-optic components, the flexible ureteroscope was transformed, resulting in improvement of image quality and weight. However, the diameters of these digital ureteroscopes have not matched those of their fiber-optic counterparts (Table 40.1).

Digital ureteroscopes were also found to have better illumination and resolution than fiber-optic flexible ureteroscopes, as well as an ability to digitally magnify images up to 1.35 times their original size (Figure 40.2) [11]. With the ability to house the image processing and

lighting within one unit, this reduced potential for water leakage into the unit, possible burns from an unattended light source, and number of cables from the unit [11].

## Flexion and deflection

Early flexible ureteroscopes were only capable of passive deflection and were limited in their ability to fully navigate the urinary tract [12]. With improvements, lever/pulley mechanisms were introduced, allowing flexion and deflection of the distal end of the endoscope. The degree of flexion/deflection depends on the configuration and capacity of the optic and illuminating components, as well as the irrigating and working channels within the shaft. This movement is further limited when an instrument such as a laser fiber or basket is introduced into the working channel. In early designs, ureteroscopes relied on both active and passive deflection such that in order to access the lower pole of the kidney, the operator could maximally deflect the tip of the ureteroscope and then, by advancing the ureteroscope further, cause passive secondary deflection by buckling slightly more proximal along the shaft [13]. With constant improvements, the deflection capabilities of ureteroscopes have improved dramatically, reaching as high as 275° for some currently available scopes (see Table 40.1). Deflection is reduced by varying degrees depending on the size and shape of the instruments passed through the working channels, with a resulting variability of impedance upon deflection by a variety of ancillary devices (Figure 40.3), as discussed later in this chapter.

## Irrigation and working channels

The last necessary feature for a flexible ureteroscope is a working and/or irrigation channel. This allows for irrigation of fluid to maintain patency and visualization of the collecting system while passing the ureteroscope through the upper urinary tract [12]. With the development of smaller optics at the distal tip, manufacturers were able

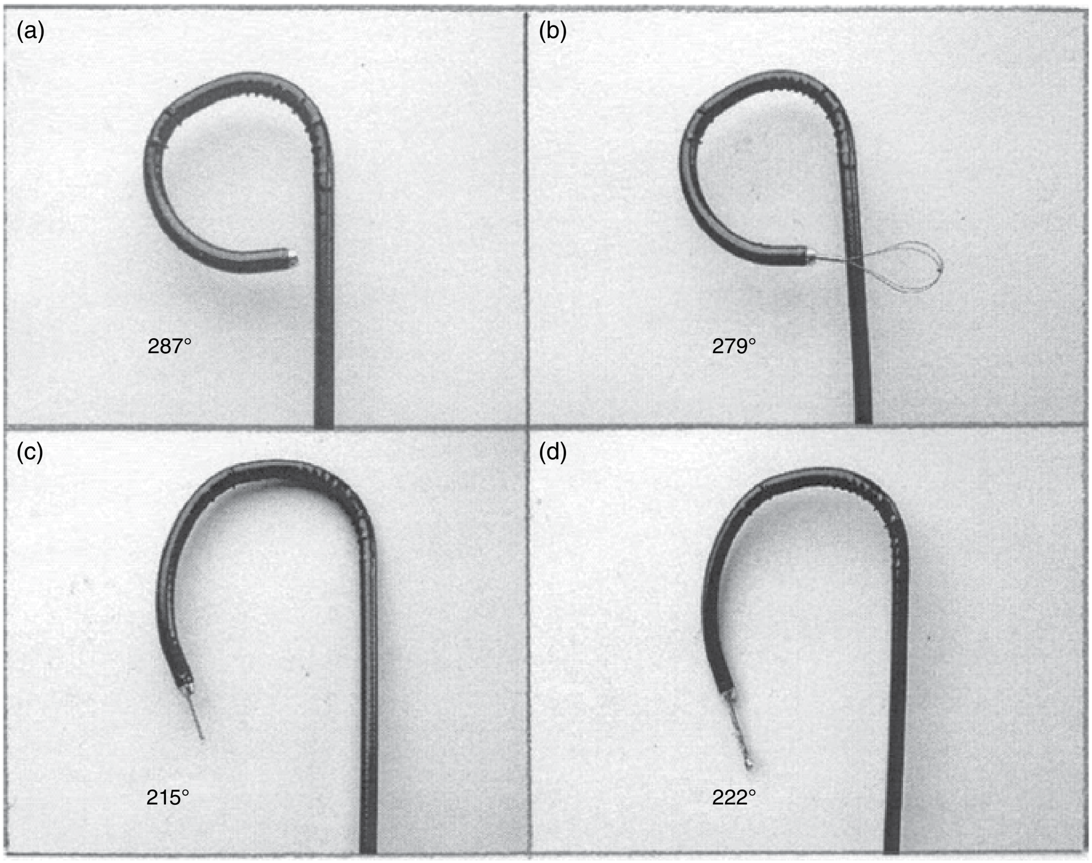

**Figure 40.3** Maximal deflection of distal tip of the DUR-8 Elite flexible ureteroscope with different endoscopic instruments in working channel [14]. (a) Channel empty; (b) 3 Fr nitinol stone basket; (c) 365 μm laser fiber; (d) 3 Fr biopsy forceps. *Source*: Chiu KY, Cai Y, Marcovich R et al. Are new-generation flexible ureteroscopes better than their predecessors? *BJU Int* 2004;93(1):115–119. Reproduced with permission of John Wiley & Sons.

to place the aperture of the working channel in a less eccentrically placed position, ultimately closer to the center, allowing more central protrusion of a passed endoscopic instrument from the working channel.

In 2004, and from this point on, a large number of studies began to evaluate improvements or lack thereof with newer generation flexible ureteroscopes compared to their predecessors [14, 15]. Chiu et al. examined the DUR-8 Elite and the Storz 11278AU, comparing these endoscopes with their older models, DUR-8 and 11274AU, respectively. Their findings showed that the two newer models had considerably better deflection of the distal tip than their respective predecessors. The deflection of all ureteroscopes examined was reduced with insertion of varying endoscopic instruments, with the 3 Fr tipless nitinol stone basket (Cook, Spencer, IN, USA) having the least impact on reduction of deflection, and the 3 Fr biopsy forceps (Richard Wolf, Vernon Hills, IL, USA) having the greatest impact on limiting the degree of deflection (see Figure 40.3). The latest-generation Cobra ureteroscope by Wolf is the first flexible ureteroscope to incorporate two working channels (Figure 40.4) [16]. It contains a 3.6 Fr and 2.4 Fr working channel, allowing unimpeded irrigation when using an endoscopic instrument. The Cobra also comes equipped with a "laser shifter", an apparatus which allows the position of the laser to be locked with minute extension or retraction.

Working channels are subject to considerable wear and tear as they are exposed to the back and forth motion of endoscopic instruments of varying degrees of rigidity and abrasiveness. The working channel is often subjected to laser damage either from misfiring within the channel or collateral damage from the laser firing too close to the aperture at the tip of the scope. Storz has introduced a coating of the distal tip of the working channel with a ceramic compound called Laserite™. This material protects the instrument from thermal damage and reduces the risk of damage and need for repairs [13].

## Current flexible ureteroscopes

There are a number of commercially available digital and fiber-optic flexible ureteroscopes (see Table 40.1). These instruments are similar in construction but have notable differences in parameters such as shaft diameter, working channel diameter, and range of deflection. Although the image and lighting mechanisms of these new generation of flexible ureteroscopes are substantially different, their functional standards with regard to working channels, irrigation, flexibility, and durability remain similar to those of their fiber-optic ancestors. However, their shaft diameters have yet to achieve the smaller sizes seen in fiber-optic flexible ureteroscopes. As the standards continue to improve, competition to make incremental improvements in the core parameters of these endoscopes continues.

### Olympus Gyrus ACMI

The Gyrus ACMI DUR-8 Elite (Gyrus ACMI, now a business division of Olympus Surgical, Orangeburg, NY, USA) ureteroscope was the first ureteroscope to have two points of active deflection. The DUR-8 Elite also offered a Moiré reduction filter which aided in reducing the honeycomb/pixilation pattern secondary to the fiber-optic bundling (Figure 40.1). The DUR-8 Elite was succeeded by the DUR-8 Ultra which offered improvement in distal and proximal shaft size and range of deflection bidirectionally, but removal of the active secondary deflection mechanism. Of significant importance was the development in 2006 of the DUR-D®, the first commercially available digital flexible ureteroscope utilizing the "chip-on-the-tip" mechanism. Its imaging capabilities were superior to those of its fiber-optic counterparts (Figure 40.2), but its deflection was slightly reduced. Nonetheless, this was a milestone achievement for the evolution of flexible ureteroscopes as it set the standard for future digital ureteroscopes.

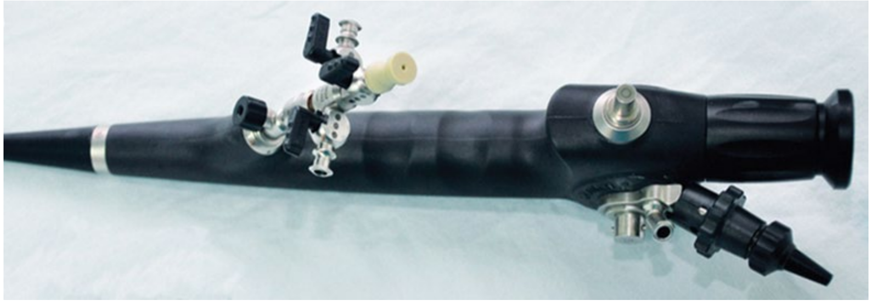

**Figure 40.4** Cobra dual-channel ureteroscope demonstrating two working channels with the laser advancement channel being of longer length and more proximal [16]. In this image, the thumb-operated "laser shifter" is visualized. *Source*: Geavlete P, Multescu R, and Geavlete B. Pushing the boundaries of ureteroscopy: current status and future perspectives. *Nat Rev Urol* 2014;11(7):373–382. Reproduced with permission of Macmillan Publishers Ltd.

In 2011, Gyrus ACMI was acquired by Olympus (Olympus Surgical, Orangeburg, NY, USA), who already had the URF-P5, offering a reduced size in diameter of the distal tip of 8.4 Fr. This was followed by the URF-P6 offering an even smaller diameter distal tip of 7.0 Fr, but also an increased range of flexion of 275° bidirectionally. Olympus has also since produced a new digital ureteroscope, the URF-V, but its specifications show a regression in design optimization with a distal tip diameter measuring 8.5 Fr and upward deflection of 180°. All working channels of the Gyrus ACMI as well as the Olympus ureteroscopes have maintained a dimension of 3.6 Fr.

### Storz

Karl Storz was one of the first manufacturers to bring the distal tip diameter to 7.5 Fr while maintaining a 3.6 Fr working channel (Karl Storz, Tuttlingen, Germany). Storz is also responsible for taking steps to reduce damage and repairs with the integration of Laserite™, giving added protection to the distal tip for thermal damage. The current Flex-X2 also boasts the ability to offer an intuitive or counterintuitive flexion/deflection lever system depending on the operator's preference. The Flex-Xc is the digital flexible ureteroscope offered by Storz. Similar to the digital ureteroscope offered by Olympus, the Flex-Xc distal tip measures 8.5 Fr compared to the 7.5 Fr distal tip offered by its Flex-X2 fiber-optic counterpart.

### Stryker®

Stryker offers the fiber-optic U500 and the digital URT-7000S/7000Si flexible ureteroscopes (Stryker Endoscopy, San Jose, CA, USA). The U-500 or Flexvision™ offers bidirectional flexion of 275° and is equipped with a dual secondary deflection and locking mechanism, allowing the operating hand to relieve strain while fully deflected. The Flexvision optic system is made up of high-density fiber bundles in order to optimize image quality. The URT-7000S/7000SI video ureteroscope utilizes "chip-on-the-tip" digital video technology, is capable of 240° of deflection, and comes equipped with a 3.6 Fr working channel.

### Wolf

The contributions of the Richard Wolf flexible ureteroscopes are of particular interest as the manufacturers have recently introduced the Cobra flexible ureteroscope with a dual working channel system (Figure 40.4). Initially, the channels were fitted to be both 3.3 Fr in diameter, however later models altered the size of these channels to 3.6 Fr and 2.4 Fr. The Cobra is capable of 270° bidirectional deflection like its Viper predecessor. Haberman et al. evaluated the single- and dual-channel Wolf fiber-optic ureteroscopes and found the dual-channel to have superior upward and downward deflection when compared to the single-channel model [17]. Wolf also manufactures a digital flexible ureteroscope, the Boa flexible ureteroscope, equipped with a 3.6 Fr working channel, bidirectional flexion of 270°, and a larger 8.5 Fr distal tip.

### Lumenis®

The standard paradigm of reusable flexible ureteroscopes has come into question, mostly due to their processing, high repair costs, and overall perceived cost effectiveness.

In light of these perceptions, Lumenis (Santa Clara, CA, USA) has manufactured the PolyScope®, a modular flexible ureteroscope. This consists of a single-use flexible multi-lumen catheter and a separate, reusable optical fiber consisting of a 10 000 pixel fiber-optic element. This endoscope is capable of tip deflection of 270° and has a working channel diameter of 3.6 Fr [2]. Yan et al. found that modular flexible ureteroscopy with holmium laser lithotripsy may be considered a feasible method for treatment of calculi with acceptable efficacy, low morbidity, and low maintenance costs [3]. Similar findings were found by Ma et al. and Ding et al. with their use of the PolyScope [4, 18].

### SemiFlex Scope™

Maxiflex™ (New Orleans, LA, USA) manufactures the SemiFlex Scope flexible ureteroscope, a disposable hybrid endoscope with a combination of a rigid proximal shaft and flexible distal shaft and equipped with a reusable eyepiece. This was one of the first ureteroscopes designed with disposability in mind and comes equipped with a 10 000 pixel optical bundle and lighting fiber as well as a 3.4 Fr working channel. It was found to have acceptable active tip deflection, field of view, and flow rate when compared to its reusable competitors [19].

### Boston Scientific

In early 2016, Boston Scientific (Marlborough, MA, USA) launched the first completely disposable digital flexible ureteroscope, the LithoVue™. This ureteroscope exhibits 270° bidirectional flexion, similar to its competitors, along with a 3.6 Fr working channel and 9.5 Fr outer diameter. The impetus for this approach involves the costs accrued due to damage, repairs, and sterilization of reusable flexible ureteroscopes, as well as the associated clinical implications. In a human cadaveric model, the LithoVue was compared with a nondisposable fiber-optic and digital flexible ureteroscope. It was reported that the LithoVue was comparable to this conventional ureteroscopes in terms of visibility and manipulation into the collecting system [1]. A unique feature of an entirely disposable flexible ureteroscope is the elimination of risk of potential transmission of microbial agents to patients via contaminated endoscopes, as has been noted with the use of endoscopes in other subspecialties [20].

## Maintenance, durability, and prevention of damage

Because of their size and components, flexible ureteroscopes are inherently fragile. They are also regularly exposed to repeated stress in the form of twisting and torqueing of the shaft in order to access difficult to reach calyces, repeated passage of laser fibers, baskets and graspers, high-energy explosions at the tip of the ureteroscope, accidental firing within the working channel, laser damage due to laser fiber fracturing, and intense heat and chemical exposure during sterilization. As flexible ureteroscopes have improved, with diminishing shaft diameters, larger and multiple working channels, and increased flexion, their clinical uses and roles have expanded, thus placing even further strain and higher demands on them and resulting in an increasing need for strength and durability.

It has been well documented that the costs involved in maintaining and repairing flexible ureteroscopes are significant and efforts must always be made to minimize instrument breakage [21]. Afane et al. were one of the first groups to evaluate the durability of flexible ureteroscopes, namely those less than 9 Fr in diameter [22]. The authors found that their endoscopes were sent for repair after an average of 6–15 uses, and cited the most common reason for endoscope repair as poor or complete loss of deflection while luminosity and irrigant flow remained relatively unchanged. In 2006, Carey et al. analyzed the frequency of ureteroscope damage at their tertiary care center and noted a number of important findings with regard to maintenance and cost [23]. The authors revealed that after initial damage has occurred, subsequent damage usually occurs more rapidly. They deduced that after a ureteroscope sustained major damage requiring repair, it may be more financially prudent to purchase a new ureteroscope as the cost of maintenance and repair after the initial repair increases significantly per case. They also found it to be more cost-effective for ureteroscopes to be processed and cleaned by dedicated professionals in the endoscopy suite, noting three potentially preventable incidents of damage requiring repair when the ureteroscope was sent for cleaning to a central processing unit. Lasselin et al. also found that significant damage to the fiber-optics occurred during endoscope disinfection [24]. Carey et al. further deduced that flexible ureteroscopes that have undergone comprehensive repair are extremely fragile, a factor which should be considered when purchasing a reusable ureteroscope [25]. Knudsen et al. examined the failure rate of DUR-D® Invisio® digital ureteroscopes over a 12-month period [26]. They found that a total of nine failures requiring endoscope repair occurred, seven of which were not covered under warranty; each repair cost US$6600. They noted that in five of the seven nonwarranty repairs, a damaged distal lens, resulting in flooding of the endoscope, was the main reason for repair.

Knudsen et al. evaluated the durability of four late model flexible fiber-optic ureteroscopes – the Wolf Viper, Olympus URF-P5, Gyrus ACMI DUR-8 Elite, and Stryker Flexvision U-500 – in a randomized prospective multi-institutional clinical trial [27]. They found no significant differences between the four endoscopes in terms of durability. The authors concluded that these newer generation flexible ureteroscopes remained fragile, although it appeared that a comparable degree of durability had been achieved in different scope manufacturers.

Digital flexible ureteroscopes have also been investigated in this regard. In 2009 Al-Qahtani et al. investigated the newer generation Olympus URF-V, used over the course of 60 cases, and noted loss of deflection, while subjective quality of the image remained the same [28]. The digital endoscopes used in this study have significantly different optical systems from those of the fiber-optic scopes in previous studies, and the mechanism for damage may follow a different pattern.

A number of general practices can improve scope durability, including following proposed recommendations for safe use and monitored training of new users [29]. In a recent analysis, Defidio et al. concluded that increased durability can be achieved by adopting a number of strict techniques including minimizing work undertaken with a fully deflected instrument, introduction of instruments through the working channel while maintaining the endoscope in a straight fashion, utilization of a laser catheter sleeve when using the 200 μm fiber, and, critical to their analysis, having a low-risk sterilization method such as Cidex® [30]. The authors duly note that a low-risk sterilization method may not be acceptable universally. In this respect, a study by Johnson et al. examined the effects of repeat sterilization with the Steris System 1® (Steris Corporation, Mentor, OH, USA) and the Sterrad® NX® (Johnson & Johnson, Langhorne, PA, USA) system on the Lumenis Polyscope, common sterilization methods that have been shown to be damaging to the optical properties of flexible ureteroscopes [31, 32]. They found the endoscopes to be durable after 100 cycles of sterilization. Muggeo et al. analyzed the cost of reprocessing flexible ureteroscopes using low-temperature sterilization for heat-sensitive ureteroscopes versus high-level disinfection [33]. They noted that low-temperature sterilization was more cost-effective on a microeconomic scale and also removed any theoretical risk of possible transmission of microorganisms.

As mentioned earlier, various mechanisms have been designed to protect scopes from laser-related thermal damage. One such mechanism is the protective sleeve fitted around laser fibers while in the working channel. Defidio et al. noted that use of the Cook laser catheter sleeve was a contributing factor in maintaining durability of flexible ureteroscopes [30]. Lusch et al. evaluated a similar device, the Scope Guardian Sheath (Mayumana, Netherlands), as well as ScopeSafe™ laser fibers. They found that the ScopeSafe fibers were effective in preventing working channel damage, with limited reduction in deflection and irrigation flow [34]. Chapman et al. showed a significant reduction in repair costs with the use of disposable laser fibers rather than reusable laser fibers, which can sustain microfractures along the fiber, leading to ureteroscope damage [35]. The authors state that although the individual cost of the disposable laser fiber is higher, this is offset by the decrease in damage to the endoscope and fewer repairs needed. Pietrow et al. also noted that their endoscopes averaged 27.5 uses before being sent for repair, suggesting that the advent and use of nitinol devices, ureteral access sheaths, and 200 μm laser fibers helped to lessen the strain placed upon the endoscope and thus minimize damage [36].

Another factor to be considered when trying to prolong the lifespan of flexible ureteroscopes is the utilization of ureteral access sheaths, as was shown by Multescu et al. [37]. It has also been found that performance of a pressure leak test following flexible ureteroscope use helped to identify damage early and avoid further damage, resulting in significant cost savings and reduction in downtime [38].

## Comparison of flexible ureteroscopes

Studies examining the capabilities and functions of flexible ureteroscopes generally focus on the main components discussed earlier: optics, flexion/deflection, and working/irrigation channels. Some further studies are also worthy of note, however. In 2008 Bach et al. evaluated, *in vitro*, five different flexible ureteroscopes and assessed the impact on deflection and irrigation flow with their working channels unloaded and loaded with various instruments [10]. The authors found similar results across all five examined ureteroscopes. They noted that deflection had no impact on irrigation flow when unloaded, and there was no impact seen on the maximum deflection when loaded with a tipless nitinol basket. The authors also noted that laser fibers and biopsy forceps limited maximum deflection, with biopsy forceps interfering with deflection more than laser fibers. Irrigation flow was also interrupted, with flow rates ranging from 62.24% to 99.1% for 1.5 Fr and 3.0 Fr instruments, respectively. Further studies have also investigated the use of smaller instruments in the working channel and their minimal impact on deflection and irrigation [39]. In 2011 Bach et al. examined the effect of instruments within the working channel and their impact on light transmission by measuring the time needed to irrigate clear an inked medium [40]. They noted that the Wolf Cobra, with its dual working channels, had the most rapid restoration of light, and the Olympus URF-P5 had the longest time needed for restoration of light, emphasizing the relationship between visualization and irrigation.

A number of studies have compared fiber-optic and digital ureteroscopes. They reveal that the digital scopes have superior resolution, with better image resolution and quality, and safety with regard to reduction of the fire hazard of xenon lights [11]. Multescu et al. in 2013 examined three different flexible ureteroscopes: the Storz Flex-Xc (digital), Olympus URF-V (digital), and the Wolf Cobra (fiber-optic) [41]. The authors noted a slight advantage with the Flex-Xc with regard to maneuverability, but overall the ureteroscopes performed similarly. The fiber-optic Cobra achieved a lower score for visibility compared to its digital counterparts, but offered adequate irrigation and subsequent visualization independent of the size of the accessory instruments used. This study also demonstrated further the impact of working devices used within the working channels and their effect on the capabilities of the ureteroscope. Lusch et al. compared the fiber-optic Storz Flex-X2 with the digital Flex-Xc, and found the digital Flex-Xc to have superior optics in clear and bloody fields and better illumination than the Flex-X2 [42]. The Flex-Xc also proved to have better overall deflection and better flow with or without accessory instruments in the working channel. A similar study by Zilberman et al. examined the digital Olympus URF-V flexible ureteroscope and compared it with the fiber-optic URF-P3, using an *in vitro* assessment of image resolution, distortion, color representation, grayscale imaging, field of view, and depth of view [43]. The digital ureteroscope was found to have a higher resolution with less distortion, and better color representation. Similar contrast was noted between the endoscopes. The digital ureteroscope produced a 5.3 times larger image and narrower field of view than the fiber-optic endoscope; the depth was not limited by the optics but rather by light for both endoscopes. Another study examining fiber-optic versus digital flexible ureteroscopes done by Somani et al. compared the Olympus

URF-V and the URF-P5 [44]. The authors noted the fiber-optic URF-P5 to have slightly less maneuverability than the digital URF-V, and the URF-V to have a reduced operative time, but overall the two endoscopes had comparable success rates. Shah et al. compared two flexible digital ureteroscopes in 2015, the CCD-based ACMI/Olympus DUR-D and the CMOD-based Olympus URF-V, and found the URF-V to offer better visibility and maneuverability [45]. Both scopes were found to have similar failure rates when compared to previous studies examining fiber-optic ureteroscopes. Improvements in general image quality were well noted with digital flexible ureteroscopes, which is not altogether surprising.

## Future directions and considerations

As flexible ureteroscopes continue to evolve, we see an expanding horizon of increasing technological possibilities both with flexible ureteroscopes as well as their ancillary devices. There is an increasing role developing for disposable flexible ureteroscopes and it is postulated that these disposable scopes may potentially decrease cost by employing them in cases where damage is more likely (i.e. large stone burden, lower pole stones, and complex anatomy) and institutions where repair costs have been found to be relatively high. These endoscopes are only entering the clinical arena, but provisional tests are showing favorable results [1–4, 18, 20]. Robotic platforms for flexible ureteroscopes are also being investigated with a view toward improving instrument stability, ergonomics, and decreased radiation exposure. Desai et al. published their results in 2008 with animal studies and further in 2011, reporting their initial clinical experience using a novel platform with a custom-designed passive ureteroscope, a steerable catheter system, and a remote catheter manipulator [46, 47]. More recently, the Avicenna robotic platform (Elmed, Ankara, Turkey) has been designed with a traditional ureteroscope and a remotely controlled robotic manipulator (Figure 40.5) [48]. This has yielded early clinical results suggesting it to be suitable and safe with significant improvement of ergonomics [7].

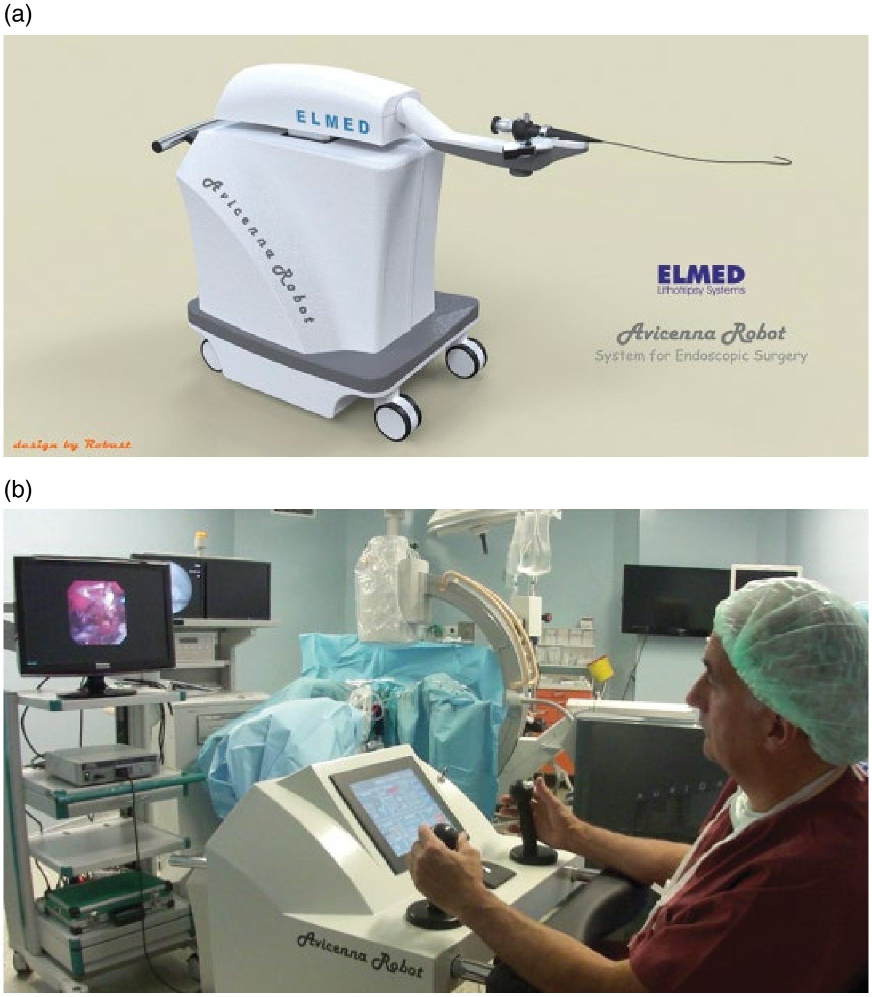

**Figure 40.5** Avicenna robot for flexible ureteroscopy [7]. (a) Manipulator for flexible ureteroscope. (b) Console with joysticks, touch-screen, and armrest. Setup to be used in conjunction with monitor, C-arm, laser, and irrigation. *Source*: Saglam R, Muslumanoglu AY, Tokatli Z, et al. ## Summary

Over the last century, the flexible ureteroscope and its technological evolution has progressed exponentially. Digital ureteroscopy is slowly replacing traditional fiber-optics, and we are already seeing an emerging role for robotics. As these instruments continue to be designed, tested, and redesigned, urologists will be tasked with determining their continued safety, efficacy, and durability.

## Introduction

It is over a century since the first recorded ureteroscopy by Young in 1912. Ureteroscopy has become the preferred surgical treatment modality for managing upper urinary tract stones due to its minimally invasive nature and satisfactory results, particularly for stones <2 cm [1]. Based on endoscope structure, ureteroscopes have developed in two categories. Semirigid or rigid ureteroscopes have a metal shaft and a synchronous tip response. These scopes have the advantages of ease of manipulation and the short learning curve that is required to use them. However, semirigid/rigid ureteroscopes still have several limitations. Semirigid scopes have a rigid and straight shaft that is capable of treating ureteral stones with satisfactory results [2]. However, the stone-free rate is relatively low for treating proximal ureteral stones due to the potential risk of retropulsion [3]. In this condition, ureteral occlusion devices are effective in reducing proximal ureteral stone migration; however, there are additional side effects [4]. Flexible ureteroscope replacement is an another solution to settle the problem of stone migration. Nevertheless, endoscope replacement during the procedure is not convenient and is likely to cause contamination as well as prolonged operation time.

Flexible ureteroscopes have a fully deflectable shaft and actively flexible tip and are thus capable of treating renal stones. However, since the flexible shaft leads to difficult manipulation, flexible ureteroscopes are not suitable for treating distal ureteral stones. Furthermore, poor maneuverability, extra costs for the ureteral access shealth, and high device vulnerability preclude flexible ureteroscopes from wider distribution [5].

To overcome the deficiencies of traditional rigid and flexible ureteroscopes, Yinghao Sun has designed and developed a hybrid ureteroscope integrating rigid and flexible features. The greatest innovation of this novel ureteroscope, is that within the body of a rigid ureteroscope is the distal flexible tip capable of active deflection, functioning with the unique capacity of both rigid and flexible ureteroscopes. Since it debuted 15 years ago, the second generation of this novel ureteroscope has come into production. After 3 years, Sun's tip-flexible semirigid ureteroscope has spread across China and is being used in more than 80 domestic urological centers, and the the number is growing. Moreover, Sun's ureteroscope has been introduced in speeches at 2014, 2015, and 2016 World Congress of Endourology annual meetings and is highly valued by international counterparts. For now, it is an alternative to a rigid or flexible ureteroscope for endoscopic lithotripsy.

## Endoscope development

In 2003, with technical help from the Olympus Corporation, Yinghao Sun and his colleague developed the first generation of the tip-flexible ureterorenoscope. This novel endoscope intergrated the flexible tip of the Olympus URF-P3 flexible ureteroscope with a rigid shaft tip. The caliber of the endoscope is 8.5 Fr at the deflectable tip and 10 Fr at the proximal end of the tapered shaft. The flexible tip is maintained in a straight axis when an accessory rigid probe is inserted in the working channel, thus making it feasible for ureteroscopic access. When the probe is withdrawn, the flexible tip can be controlled for active deflection to explore the renal collecting system. The flexible part on the tip is 60 mm in length, which allows active dual deflection up to a maximum of 180°. When a 200 mm laser fiber is inserted, the maximal deflection angle decreases to 110°. This active deflection performance is almost the same as the Olympus URF-P3 flexible ureteroscope. In addition, the active deflection manipulation was parallel to that of the URF-P3. The operator is able to deflect the flexible tip upwards

and downwards by activating the deflection lever on the handpiece. In order to fit the flexible part, the working channel of the composite ureteroscope is 3.5 Fr in diameter. Although it is rather smaller than some rigid/semirigid ureteroscopes, the caliber is sufficient for most ancillary instruments [6].

In the subsequent clinical application reported in 2010, a total of 175 patients with renal calyceal calculi who underwent ureteroscopic lithotripsy using this first-generation tip-deflectable ureteroscope with a holmium laser were retrospectively reviewed. Some 87.5% of the patients were treated successfully using the ureteroscopic approach. Failures included 4.6% of the patient who had severe torsion of the ureter, and in another 7.4% patients the procedure failed to find a lower pole calyceal calculus. The success rate of stone clearance (defined as any single residual fragment less than 2 mm) after 1 month was 83%. Based on the initial study result, this new ureteroscopic technique was seen to have some definite advantages when compared with other types of traditional stone treatment. First, patients requiring a ureteroscopic approach with multiple stones in the renal calyces and the proximal ureter can have them removed within a single procedure using the novel ureteroscope. This avoids the necessity for secondary procedures or a change to flexible ureteroscopy modalities. Second, the composite ureteroscope is manipulated in the same way as the traditional semirigid ureteroscope, only with an added lever for deflection control. This is considered to make the endoscopic procedure easier. Third, this hybrid ureteroscope might have a longer life expectancy than a traditional flexible ureteroscope, which will have economic benefits in lower-income countries in particular.

Some limitations were found that require improvement. For example, only if the rigid accessory probe was inserted could the flexible tip be maintained in a straight axis, allowing easier passage through the intramural ureter and then anteriorly over the iliac vessels with enough maneuverability to negotiate narrow ureters. As the hybid ureteroscope had only one working channel, there was a lack of space for working instruments in the working channel for lithotripsy when the probe was inside. Additionally, the 180° dual deflection did not allow a full exploration of the collecting system in some cases. Moreover, the flexible part of the endoscope was found to be not long enough to fully inspect the renal calyces since it was only 60 mm in length.

## Current Sun's scopes

In 2012, Yinghao Sun, cooperating with the Hawk Endoscopes Corporation (Hangzhou, China), developed and produced a new version of the tip-flexible semirigid ureterorenoscope, which became known as Sun's ureterorenoscope. This endoscope on improved some of the deficiencies of the previous version and demonstrated strong practicality and universality. In the 4 years after that, Sun's ureterorenoscope spread rapidly across China and it is now gaining momentum not only in China but also in the wider Asian commercial endoscope market.

### General properties

Sun's ureterorenoscope involves similar basic components as a common semirigid ureteroscope, including an optical channel for image provision, fiber-optic bundles for light transmittal, and a working/irrigation channel. Sun's ureterorenoscope has an additional deflection mechanism for active flexible tip movement. To achieve the intergrated functions of both traditional rigid and flexible ureteroscopes, Sun's ureterorenoscope has a unique combination structure that consists of a semirigid ureteroscope with a deflectable part on the tip of the shaft and a rigid metal sheath. These two parts are disassembled during sterilization and reassembled for use. The semirigid and flexible working modes can be switched between by setting the sheath in a retracted or nonretracted position. With development in fiber-optic systems and use of materials, Sun's ureterorenoscope provides better imaging quality, increased active deflection, and larger working channel within an even smaller shaft compared with the previous version. Details of some main properties are discussed in the following sections. See Figure 41.1.

### Optics, angle, field of view, and eyepiece

Similar to the most current semirigid and flexible ureterorenoscopes, Sun's ureterorenoscope has a fiber-optic system that includes two light bundles and one optical bundle to provide light and image transmission. This maintains full visualization during scope passage through the tortuous ureter without leading to crescent-shaped defects on the scope eyepiece if using the traditional rod-lens system, and even allows navigation with a large range of active deflection in the renal collecting system. The two sets of light bundles are helpful to eliminate shadows when any working instrument is inserted. The fiber-optic bundles' pixel count is 10 000, which is much more than that of most current fiber flexible ureteroscopes (6000 for Olympus URF-P5 and 6000 for Karl Storz Flex-X2) [7]. Thus it provides better image quality than most fiber flexible ureteroscopes (see Video 41.1).

The angle of view of Sun's ureterorenoscope is 10°. This facilitates passage of the scope when encountering a tortuous ureter and allows immediate visualization when a working instrument emerges from the tip. Sun's ureterorenoscope has a field of view of 90°, comparable with the current flexible ureteroscopes on the market.

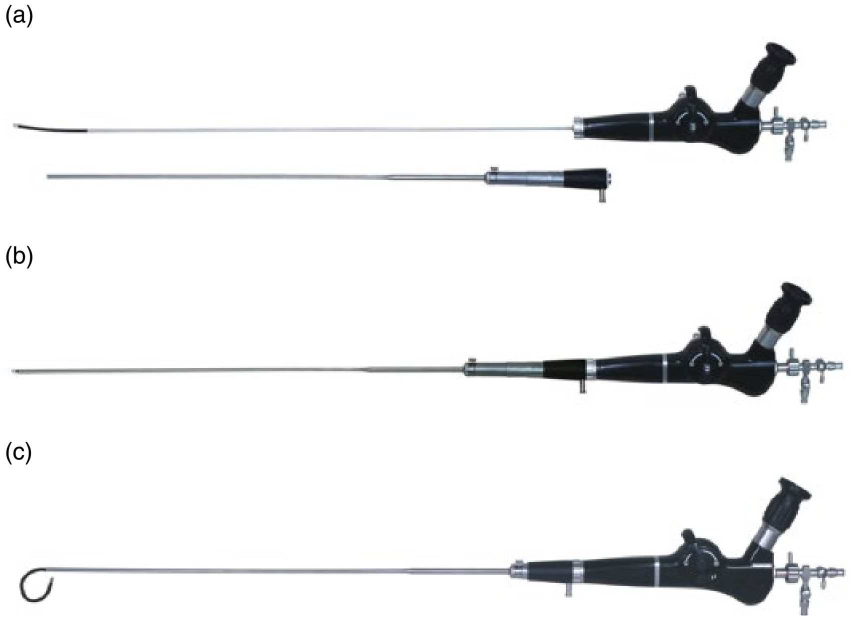

**Figure 41.1** Components of Sun's semirigid ureterenoscope. (a) Dissembled components of the ureterenoscope including a semirigid ureteroscope and a rigid sheath; (b) ureterenoscope in rigid endoscope mode; (c) ureterenoscope in flexible endoscope mode.

To permit introducing a straight working instrument, an offset ocular eyepiece design was included. This eyepiece is fixed on the handpiece and can be connected to the camera.

## Dimensions and the scope tip

Similar to most current semirigid ureteroscopes, Sun's ureterorenoscope is designed with a graduated stepless tapered design, so the shaft is small in diameter at the distal tip and the caliber enlarges gradually towards the proximal end. As the outer rigid sheath and the inner tip-flexible ureteroscope have to be assembled together when the endoscope is in use, it is the caliber of the sheath that affects the ureteroscope's advancement. The diameter of the ureterorenoscope, which is 8.4 Fr at the distal tip and 9.8 Fr at the proximal end, is bigger than that of some flexible ureteroscopes and it might be thought that it would require ureteric orifice dilatation more frequently. In clinical application, Sun's ureterorenoscope still proved to have a 91.9% success rate for endoscope advancement without dilation [8]. This result is even better than that of the 8/9.5 Fr semirigid ureteroscope, as reported in [9]. Despite the current available flexible ureteroscopes having an even smaller shaft [10], it should be noted that the ureteral access sheath (UAS) is recommended in flexible ureteroscopy [11]. When compared with the most commonly used UAS (12/14 Fr), the caliber of Sun' ureterorenoscope is smaller, showing no disadvantage in endoscope dimension for advancement.

The length of Sun's ureterorenoscope shaft is 425 mm, allowing full access to the renal calyces in most patients. Also, it is worth mentioning that the rigid sheath of Sun's ureterorenoscope has a three-stage retractable structure in the proximal part of the shaft. This allows the sheath be locked at three different lengths, allowing variable extension of the deflectable tip to accommodate different requirements. As the retractable sheath can be fixed to the inner scope but with separate full 360° rotation, the sheath bears most of the torque resistance, allowing the inner shaft to rotate freely. All the rotation manipulation movements transfer directly to the tip of the endoscope, greatly improving the torque stability.

When the rigid sheath and the inner endoscope are assembled, the inner flexible tip is 3 mm beyond the distal end of the rigid sheath. Like with current semirigid ureteroscopes, Sun's ureterorenoscope has a beveled tip design which is only 8.2 Fr in diameter. This facilitates entrance into the ureteric orifice and minimizes iatrogenic damage.

## Working channel and irrigation

Sun's ureterorenoscope incorporates a single working channel. This 3.6 Fr working channel passes through from the lower part of the handle to the tip of the endoscope. This size is the same as that of the majority of flexible ureteroscopes, and is capable of introducing most accessory instruments including the guidewires, laser fibers, stone baskets, and biopsy forceps often involved in ureteroscopic surgery. This working channel is eccentrically located in the shaft and thus has less impact on deflection when working instruments are inserted and reduces distortion of the deflectable tip.

When a working instrument is being used, the larger the endoscopic working channel is, the more space is left in the lumen. This suggests that ureteroscopes with larger working channels provide more irrigation flow than those with small channels [12]. Comparisons of Sun's ureterorenoscope (working channel 3.6 Fr), a semirigid ureteroscope (OES Pro, Olympus, Japan; working channel 4.2 Fr), and a flexible ureteroscope (URF-P5, Olympus; working channel 3.6 Fr) showed that, due to the smaller working channel, Sun's ureterorenoscope had a lower irrigation flow rate than the semirigid ureteroscope. Nevertheless, Sun's ureterorenoscope provided more irrigation flow than the most common fiber-optic flexible ureteroscope which had the same working channel in size. This might be attributable to the total flexible lumen generating more resistance than a straight tract [13].

Despite there being only one working channel in the shaft, Sun's ureterorenoscope has a unique method for outflow not seen in other ureteroscopes. The little space between the inner scope and the rigid sheath has been taken full advantage of as a separate "outflow channel," which passes along the sheath from the holes around the distal end to the outlet at the proximal end. This novel design is considered to be helpful in providing continuous irrigation flow for a clear view.

## Deflection mechanism

As it was designed to be capable of inspecting the collecting system and treating renal stones, Sun's ureterorenoscope has an actively deflecting tip at the distal end of rigid shaft. When the outer sheath and the inner endoscope are assembled together and the sheath is fully retracted, the 90 mm deflectable tip can be used for retrograde intrarenal surgery. Similar to a flexible ureteroscope, the flexible tip of Sun's ureterorenoscope is controlled by moving the lever on the handpiece (upward deflection on the lever causes the scope tip to move downward, and vice versa). The ureterorenoscope has a dual deflection of 250° upward and 270° downward to secure full access to all calyces (see Figure 41.2). According to a previous test reported by Sun et al. [6], a decrease in deflection with various working instruments was observed in both Sun's ureterorenoscope and a flexible ureteroscope (URF-P5). However, Sun's ureterorenoscope showed less deterioration in deflection than the flexible ureteroscope with the same working instrument. The maximum downward deflection with a 200 μm laser fiber was 249° for Sun's ureterorenoscope and 226° for the flexible ureteroscope. Similar results were also found when a 1.7 Fr stone basket was used with the two endoscopes (see Figure 41.3). This demonstrated that Sun's ureterorenoscope has identical active deflection to a conventional fiberoptic ureteroscope, and that relatively high deflection is still retained when certain working instruments are inserted.

## Column strength

It has already been demonstrated that the more rigid the shaft is, the more column strength the endoscope should have. Due to their totally flexible structure, flexible

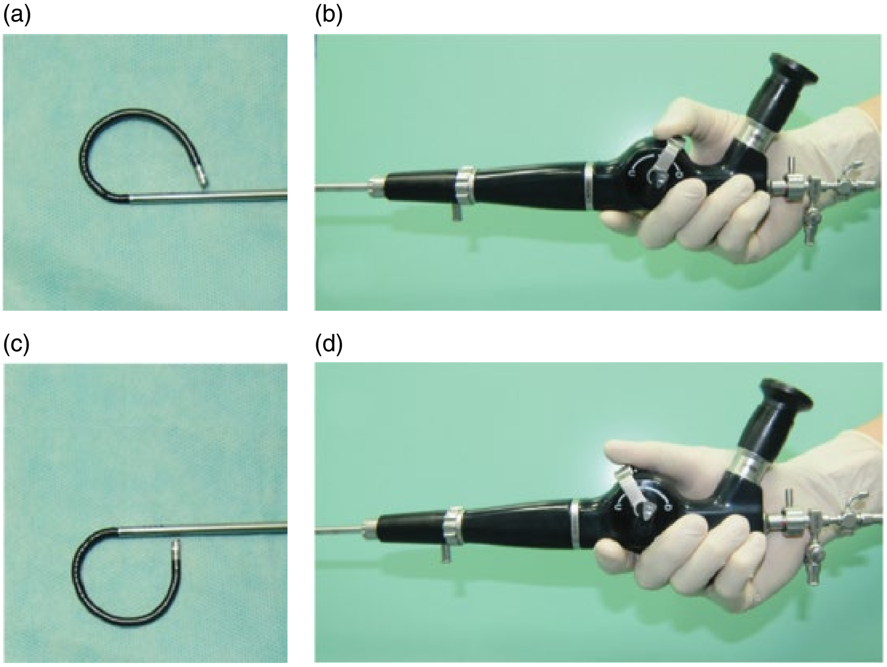

**Figure 41.2** Tip manipulation of the Sun's tip-flexible ureterorenoscope. (a, b) Lever moves downwards to control the upward deflection on the flexible tip; (c, d) lever moves upwards to control the downward deflection.

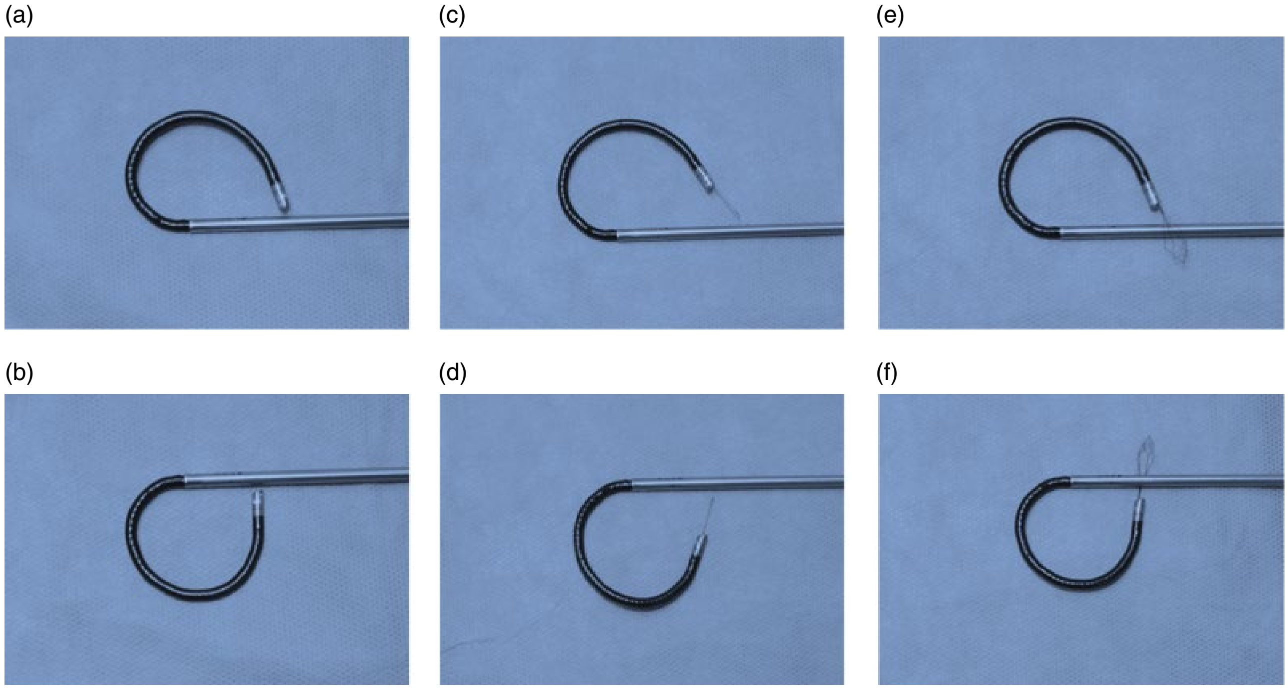

**Figure 41.3** Dual deflection of Sun's ureterorenoscope with different auxiliary instruments. (a, b) With empty working channel; (c, d) with 200 μm laser fiber; (e, f) with 1.7 Fr basket.

ureterorenoscopes are more fragile than semirigid ureteroscopes. Despite the shaft strength of the latest flexible ureteroscopes having been greatly improved through technical developments, they are still more likely to buckle [14]. As a novel composite ureteroscope, the majority of Sun's ureterorenoscope shaft is made of rigid materials, which contributes to a crush resistance that is approximately comparable to a common semirigid ureteroscope. In a study by Yinghao Sun [13], endoscope stability was assessed and compared between Sun's ureterorenoscope and a semirigid ureteroscope (OES Pro), which has the shaft caliber. Several bending forces up to 1.5 kg were applied at the proximal third of the shaft of both scopes. The subsequent deviation, defined as the angle of the endoscope tip from the baseline horizontal position, was tested as a measure of the column's strength. Both the Sun scope and semirigid ureteroscope presented a force-dependent increase in deviation angle. Although Sun's ureterorenoscope showed relatively higher deviation, the difference between the two ureteroscopes was only less than 1°. Plus, as the maximum deflection caused by the bending forces was no more than 50 mm and would not lead to scope failure, Sun's ureterorenoscope was proved to be sturdy enough for retrograde ureteroscopy.

## Light source

Traveling through the fiber bundles, the light is transmitted to the tip of the endoscope from the source lamp. Sun's ureterorenoscope incorporates two fiber light bundles on the left and the right side of the optic-transmitting bundle, eliminating any shadows cast by working instruments. Sun's ureterorenoscope has a universal light port that can use most current light sources including halogen (150 W) and xenon (300 W). With automatic light-sensing functions, these light sources can adjust the brightness to current requirements during ureteroscopic procedures.

## Passive deflection

In 2015, the latest version of Sun's ureterorenoscope released onto the market. In addition to the common features and structure of the previous version, this third-generation hybrid ureteroscope incorporated a secondary passive deflection structure (see Figure 41.4). This mechanism was achieved by adding a deflectable shaft of 40 mm in length proximal to the point of the actively deflectable tip. This segment cannot be controlled for dual deflection but is passively deflected on contact with renal tissue. This structure has the same function its the counterpart in flexible ureteroscopes, permitting an even larger range of deflection for access to lower pole calyces [15]. Additionally, the passive deflection part effectively lengthens the flexible shaft, allowing better inspection in cases with moderate hydronephrosis or with a long lower infundibulum.

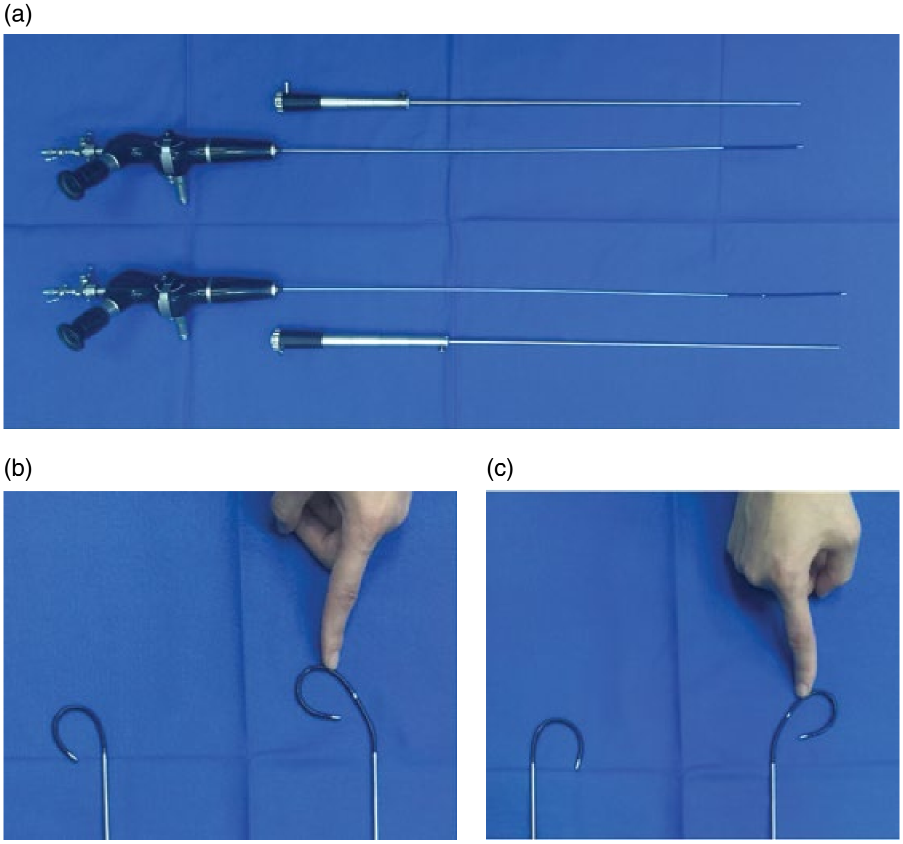

**Figure 41.4** Comparisons between the second and third versions of Sun's ureterorenoscope. (a) Overall appearance of the two endoscopes (the second-generation scope is shown at the top); (b, c) dual passive deflection of the latest version of the endoscope.

## Ureteroscopic surgery with a flexible-tipped ureterorenoscope

In the past two decades, technical improvements, such as endoscope miniaturization and imaging quality enhancement, as well as a wider variety of accessory tools, have led to a rapid gain in the popularity of ureteroscopy. These revolutionary advances have widely increased the indications for ureteroscopy, and made it possible to manage all ureteral and renal stones.

As the stone-free rate (SFR) of endoscopic surgery is considered superior to that of extracorporeal shock-wave lithotripsy and comparable to that of percutaneous nephrolithotomy for the management of either ureteral or renal stones of less than 20 mm, the European Association of Urology and American Urological Association guidelines [11] have suggested that ureteroscopy may be considered as a first-line treatment modality for upper urinary tract stones. Although the SFR for upper urinary tract stones is satisfactory, some limitations still remain. Semirigid ureteroscopy for distal or mid-ureteral stones achieves good stone clearance; however, when stones are located in the proximal ureter, stone fragments may easily migrate into the kidney during lithotripsy. Although flexible ureteroscopy has demonstrated high levels of renal stone clearance, it remains a less durable modality due to the totally flexible shaft.

In order to overcome the limitations associated with conventional ureteroscopy, Sun's ureterorenoscope was developed to be used in the treatment of ureteral and renal stones with no requirement for endoscopic alternation. In this section, details of the ureteroscopic surgery using Sun's ureterorenoscope are discussed.

### Indications

As the SFRs from distal and mid-ureteroscopic lithotripsy are claimed to be superior to that from shock-wave lithotripsy, ureteroscopy has become the first choice for treatment of stones [16]. In ureteroscopic surgery using Sun's ureterorenoscope, the inner endoscope and the outer sheath are assembled together. When the outer sheath is not retracted and the inner deflectable tip is fully inside, the endoscope has a fully rigid shaft, and can be used as a common semirigid ureteroscope. Stones located in the distal or mid ureter can be disintegrated by laser lithotripsy and extracted using a stone basket with ease during ureteroscopy.

Although SFRs of approximately 81–94% can be achieved by semirigid ureteroscopy for distal and middle ureteral stones, this decreases to 77% for proximal ureteral stones due to the potential for retropulsion [17]. Since semirigid ureteroscopes are not capable of active deflection and so cannot give access to the renal calyx, ureteral occlusion devices are always required to reduce proximal stone migration [2]. With Sun's ureterorenoscope the problem of stone migration is easily solved. Once stone retropulsion occurs, the surgeon can advance Sun's endoscope to the pelvic brim and retract the sheath, using the deflectable tip to allow access to the renal calyx to continue stone fragmentation. This advancement greatly improves the SFR for proximal ureteral stones by ureteroscopy, and thus allows Sun's ureterorenoscope to cover all parts of treating ureteral stones.

Being 90 mm in length, with a 250°/270° dual deflection tip, Sun's ureterorenoscope can allow access to almost any part of the renal collecting system. This makes it possible to treat renal stones as if using a flexible ureterosocope. Nevertheless, it should be noted that patients with hydronephrosis of >30 mm in diameter on ultrasonography are usually excluded because of the increased difficulty in inspecting the collecting system and in accessing some lower pole calyces [11].

## Equipment

Like all endourologic surgery, a procedure involving Sun's ureteroscope should always take place in a lead-shielded operating room, as retrograde pyelography and X-ray examination are routinely required. Other basic equipment is essential, including guidewires, contrast medium, laser lithotripsy, stone retrieval devices, irrigation system, as well as biopsy forceps (if needed).

Although an open-end ureteral catheter is not required as retrograde pyelography can be directly performed with the ureterorenoscope, guidewires are still necessary as they enable the ureteroscope or the ureteral dilator to advance through the ureter. Super-stiff wires are more likely to be used when a tortuous ureter needs to be straightened. A 0.035 inch angled-tip hybrid hydrophilic guidewire is always recommended as they can become be very slippery and atraumatic when absorbing water. Besides, this type of guidewire has sufficient rigidity for endoscope advancement and easy passing of impacted stones in the ureter.

Many lithotripsy devices have had technical developments, and proved to be safe and effective for ureteroscopy. As for Sun's ureterorenoscope, holmium:YAG laser is the preferred device. The laser fiber has smaller size than other lithotripsy devices such as in pneumatic and ultrasonic lithotripsy, which is suited to the 3.6 Fr working channel of the Sun's endoscope. In addition, the 200 μm laser fiber is very flexible and does not hinder the active deflection of the flexible tip. With these features, a holmium:YAG laser allows renal stone fragmentation through Sun's ureterorenoscope even if the stone is located in the lower renal calyx.

According to a matched-pair study, a semirigid ureteroscope that was almost the same size as Sun's ureterorenoscope required a ureteral dilation rate of 15% [18]. This result might suggest that the potential dilation requirement for tip-flexible ureteroscopy is likely to be over 10%. By now, it is widely accepted that ureteral balloon dilators are much safer for accessing anatomically tight or strictured segments of ureter than traditional ureteral dilators. Generally, a 40 mm dilator with 12 Fr balloon is sufficient for application of Sun's ureterorenoscope.

It remains controversial whether or not fragment extraction should be performed during endoscopic surgery. Despite the fact that most stone retrieval devices could be inserted into Sun's ureterorenoscope, stone fragment retrieval is not recommended as a routine procedure during tip-flexible ureteroscopy. As the inner diameter of the rigid sheath of Sun's endoscope is only 8.2 Fr, which is not large enough for stone extraction, like the UAS used in flexible ureteroscopy, it is required that Sun's ureterorenoscope is totally withdrawn and readvanced when retrieving stone fragments. This may significantly increase the operation time, and may also be associated with increased potential for damage. Thus, nitinol tip-less baskets and graspers are only used for stone relocation when treating difficult lower pole stones or whenever stone component analysis is required.

Irrigation devices are used to actively create a space either in the renal collecting system or in the ureter, to work in and to provide clear visualization. Several varieties of irrigation device can be selected for tip-flexible ureteroscopy. Some sorts of irrigation pump are capable of providing continuous-pressure controlled flow, warmed to body temperature. These devices are easy and convenient in use, but they do have a potential risk of over-infusion that might cause pyelolymphatic or pyelovenous backflow, which is associated with subcapsular effusion or subcapsular hematoma [19]. Besides, pump irrigation is more likely to cause stone retropulsion in the treatment of proximal ureteral stones [20].

An irrigation hanging bag is another simple irrigation device and provides flow with stable pressure. It has the obvious advantage of safety whereby the irrigation flow will stop by itself if the intrarenal pressure exceeds the pressure associated with the bag height, helping to prevent over-infusion. However, it also has the vital disadvantage that irrigation is not flexible and constant visualization of the pressure might not be maintained in complicated situations. During tip-flexible ureteroscopy, irrigation by an assistant using a hand-held syringe is preferred, as it allows safe and flexible control of the force with which the irrigation flow is delivered. Nevertheless, this irrigation modality requires the assistant to be experienced and judicious. Normally, saline is the best choice.

### Step-by-step ureteroscopic access

Before use, Sun's ureterorenoscope should be carefully examined to ensure its encapsulation, deflection, retractable configuration, and image clarity are in order. The endoscope should be sent for repair if major damage is found. The surgeon should hold the endoureterorenoscope handpiece with the dominant hand, keeping the thumb on the deflection lever. The other hand should be used to hold the penis while advancing the endoscope and rest in a comfortable position during inspection and lithotripsy. The surgeon should be seated during tip-flexible ureteroscopy rather than standing, as for flexible ureteroscopy [21].
